Banks as Patient Fixed-Income Investors*

First draft: February 2014
This draft: January 2015

Abstract

We examine the business model of traditional commercial banks when they compete with shadow banks. While both types of intermediaries create safe “money-like” claims, they go about this in different ways. Traditional banks create safe claims by holding illiquid fixed-income assets to maturity, and they rely on deposit insurance and costly equity capital to support this strategy. This strategy allows bank depositors to remain “sleepy”: they do not have to pay attention to transient fluctuations in the market value of bank assets. In contrast, shadow banks create safe claims by giving their investors an early exit option requiring the rapid liquidation of assets. Thus traditional banks have a stable source of funding, while shadow banks are subject to runs and fire-sale losses. In equilibrium, traditional banks have a comparative advantage at holding fixed-income assets that have only modest fundamental risk, but are illiquid and have substantial transitory price volatility, whereas shadow banks tend to hold relatively liquid assets.

* Hanson, Shleifer and Stein are from Harvard University, and Vishny is from the University of Chicago. We are grateful to seminar participants at the 2014 NBER Spring Corporate Finance Meeting, the 2014 NBER Macro, Money and Financial Frictions Summer Institute, the Federal Reserve Bank of San Francisco, Harvard University, NYU Stern, UC Berkeley Haas, and USC Marshall for helpful comments, as well as to Malcolm Baker, John Campbell, Eduardo Dávila, Harry DeAngelo, Doug Diamond, Mihir Desai, Gary Gorton, Robin Greenwood, Bengt Holmstrom, Arvind Krishnamurthy, David Scharfstein, René Stulz, Adi Sunderam, Paul Tucker, Annette Vissing-Jorgensen, and Yao Zeng for valuable suggestions. We also thank Yueran Ma for excellent research assistance.
I. Introduction

What defines the business model of traditional banks in a modern financial system where they compete with market-based intermediaries such as “shadow banks”? To address this question, we present a model in which traditional and shadow banks co-exist in the marketplace. We begin with the premise that the primary function of both types of intermediaries is to create safe, “money-like” claims that are of value to households because they are useful for transactions purposes (Gorton and Pennacchi 1990, Stein 2012, DeAngelo and Stulz 2014). However, traditional banks and shadow banks invest in different portfolios of assets to support such claims. Traditional banks hold illiquid fixed-income assets, such as long-term securities and loans, which may be subject to substantial price fluctuations but are relatively safe in the long run. To hold such assets, they maintain a costly equity cushion in their capital structure, but also rely on deposit insurance and other elements of the government safety net. This strategy allows bank depositors to remain “sleepy”: they do not have to pay attention to transient fluctuations in the mark-to-market value of bank assets and never run. In contrast, the shadow-banking system—intermediation chains that often involve money-market funds—relies less on the government safety net and costly equity capital. For shadow banks, manufacturing money-like claims requires them to hold more in the way of relatively liquid assets that can be easily sold at only a modest discount should their investors decide to exit.

We see asset fire sales as a key source of illiquidity. In our model, asset liquidations temporarily push prices below fundamental value. So, on the one hand, traditional banks’ more stable deposit funding structure has an advantage: it enables them to hold investments to maturity, riding out transitory valuation shocks until prices revert to fundamental values. On the other hand, funding stability is expensive due to higher costs of equity capital and regulatory compliance. Because the endogenous fire-sale discount is greater when shadow banks hold more of an asset, this tradeoff pins down the equilibrium holdings of any given asset across intermediary types. The most liquid assets are held entirely by shadow banks, while the less liquid (but still fundamentally safe) assets are held entirely by commercial banks. When an asset is held by both intermediary types, the relative holdings of banks and shadow banks must be such that the expected loss to a shadow bank from liquidating an asset at a temporary discount to fundamental value is just balanced by the added cost a traditional bank pays for more stable funding.

This logic leads to our main finding: for traditional banks there is a critical synergy between the asset and liability sides of the balance sheet. Issuing stable money-like claims is complementary
with investing in fixed-income assets that have only modest fundamental risk, but are relatively illiquid and may have substantial exposure to interim fire-sale risk and the accompanying transitory price volatility. In our view, this synergy between funding structure and asset choice is at the heart of the modern business of commercial banking, and is what fundamentally distinguishes traditional banks from shadow banks: traditional banks are patient investors that can invest in illiquid fixed-income assets with little risk of being interrupted before maturity.

While our formal model emphasizes fire sales (Shleifer and Vishny 1992), our message would also emerge in other models in which early liquidation can occur at prices below fundamental value. For example, early liquidation can be costly in models that combine noise trader shocks with limited arbitrageur risk-bearing capacity (DeLong et al 1990, Shleifer and Vishny 1997). Alternatively, liquidation costs could come from adverse selection (Gorton and Pennacchi 1990, Dang, Holmstrom, and Gorton 2013). The general point is that transitory non-fundamental movements in asset prices are central to understanding financial intermediation, and especially the connection between the asset and liability sides of intermediary balance sheets. A stable funding structure is an important source of comparative advantage for holding assets that are vulnerable to transitory price movements. In this regard, traditional banks are similar to deep-pocketed arbitrageurs who specialize in fixed-income assets.

It is important to stress that what our model actually pins down is not literally the roles of different types of legal institutions (e.g., commercial banks or money market funds), but rather the equilibrium mix between two intermediation strategies that use risky assets to back money-like claims. For any given asset, our model asks how much of its total supply will be intermediated using a “stable funding strategy” that relies on an equity cushion and insured deposits, and how much using an “unstable funding strategy” where investors protect the safety of their claims with an early exit option. The interdependencies between asset characteristics and funding strategies are the true equilibrium outcomes of our model. Of course, in reality there can be a close correspondence between funding strategies and specific legal forms. In particular, when intermediaries are distinguished by their access to deposit insurance and the lender of last resort, commercial banks are the dominant institutional vehicle for implementing the stable funding strategy. And we primarily associate the unstable funding strategy with the so-called shadow banking system.

We motivate our analysis in Section II by presenting some stylized facts about the assets and liabilities of modern commercial banks. We show that banks have significant holdings of relatively illiquid long-term fixed-income securities, such as asset-backed securities, mortgage-backed
securities, and corporate bonds. At the same time, banks generally avoid the most liquid debt securities, such as short-term money-market paper and Treasuries, as well as highly risky securities such as equities. We view these facts as important clues for understanding the business of commercial banking. In Section III, we present our model of alternative strategies for supporting money-like claims, and show how commercial and shadow banks coexist in equilibrium. We then turn to some evidence bearing on our model’s key predictions about the connections between the asset and liability sides of intermediary balance sheets.

Section IV briefly takes a historical look at the U.S. commercial banking industry. We find that prior to the introduction of federal deposit insurance, U.S. commercial banks followed a strategy that resembles that of shadow banks today. Like today, a commercial bank in, say, 1870 was in the business of taking deposits and thereby offering its customers safe money-like claims. At the same time, commercial banks in 1870 held assets with much shorter maturities, and experienced more runs, than they do today. The shift of commercial bank assets to longer-maturity loans and long-term securities can be linked to the introduction of deposit insurance, as our model predicts.

Another way to examine the predictions of the model is to look at the asset and liability structures of financial institutions more broadly. In Section V, we use the Financial Accounts of the United States (formerly the Flow of Funds) to provide some contemporary aggregate evidence addressing the model’s key predictions. In the data, looking across fixed income asset classes, today’s traditional banks have a larger market share in more illiquid assets, be they loans or securities. Similarly, looking across financial intermediary types, intermediaries with more stable funding such as traditional banks have asset portfolios that are more illiquid. In this way, our model yields a novel synthesis of several aggregate facts about the structure of financial intermediation.

Our paper relates to several strands in the literature. Our starting point is the liability-centric view of banks, which holds that an important part of banks’ value comes from their ability to manufacture safe liabilities.1 This view helps make sense of the fact that, in contrast to nonfinancial firms, banks have capital structures that are highly homogenous in both the cross section and the time series: they are almost always highly deposit-financed. At the same time, this liability-centric

---

view does not explain why banks hold illiquid loans and securities.² To the contrary, the liability-centric view has led some observers to advocate narrow banking, whereby bank-created money is backed entirely by safe liquid assets, such as Treasury bills (see Pennacchi 2012). As a positive description of commercial banking, narrow banking is very far from what we observe in the world, and is unlikely to break even. The challenge is to understand why banks simultaneously finance themselves with deposits and hold long-term and illiquid fixed-income assets.

A second group of theories explicitly addresses the question of what ties together the asset and liability sides of bank balance sheets—i.e., why is it that the same institutions that create private money choose to back their safe claims not by investing in T-bills, but rather by investing in loans and other relatively illiquid assets? What is the synergy between the two activities? In a classic contribution, Diamond and Dybvig (1983) argue that banks allow households who are unsure of the timing of their consumption needs to more efficiently invest in long-lived projects which are costly to interrupt early.³ Diamond and Dybvig emphasize deposit insurance as the source of stability that keeps depositors sleepy and prevents runs. We use this observation to address a question not taken up by Diamond and Dybvig: what types of assets is it optimal for deposit-insured banks to hold?

Several other studies have focused on potential complementarities between banks’ assets and liabilities. Diamond and Rajan (2001) suggest that the fragility of runnable bank deposits disciplines bank management, enhancing the value of illiquid bank loans. Kashyap, Rajan, and Stein (2002) highlight the similarities between demand deposits and loan commitments, and the ability of an institution that offer both products to economize on costly liquidity buffers; Gatev and Strahan (2006) provide supporting evidence for this view. Gennaioli, Shleifer, and Vishny (2013) also argue that a central function of banks is to provide safe claims, but focus on asset-side diversification and tranching as technologies for backing such safe liabilities. Relatedly, DeAngelo and Stulz (2014) emphasize diversification and risk management strategies to reduce the riskiness of bank assets.

Our work also connects with several other themes. First, a number of papers explore the joint roles of banks and securities markets in allocating credit and satisfying the demand for liquidity (Holmstrom and Tirole 1997; Diamond 1997). Second, several papers study the shadow banking system and its role in the financial crisis (Brunnermeier and Pedersen 2009; Coval, Jurek,

² Asset-centric theories of banking, such as those that see banks as delegated monitors (Diamond 1984), do not draw a distinction between banks and other non-bank lenders, which we see as critical.

³ Taken literally, the Diamond-Dybvig model does not admit a rationale for banks to hold marketable securities; see Jacklin (1987). Taken less literally, the model makes no predictions on the kinds of assets banks would hold.
and Stafford 2009a and 2009b; Shleifer and Vishny 2010; Gorton and Metrick 2010 and 2011; Diamond and Rajan 2011; Shin 2009; Stein 2012; Gennaioli, Shleifer, and Vishny 2012 and 2013; Kacperzcyk and Schnabl 2013; Krishnamurthy, Nagel, and Orlov 2013; Chernenko and Sunderam 2013; Sunderam 2014; Weymuller 2013, Moreira and Savov 2014). Finally, a few recent papers measure the mismatch between the liquidity of intermediary assets and liabilities (Brunnermeier, Gorton, and Krishnamurthy 2011 and 2013 and Bai, Krishnamurthy, and Weymuller 2013).

II. Motivating Evidence

A. Fact 1: Bank liabilities are highly homogeneous

Banks’ liability structures are highly homogeneous: banks are almost always financed largely with deposits. This finding holds both in the cross-section and over time. In the cross-section, Table I shows various balance sheet items as a share of total assets at the end of 2012 for US commercial banks. To assess the cross-sectional heterogeneity in balance sheet, we show the value-weighted average share, the 90th percentile, and the 10th percentile for each item. To avoid the idiosyncrasies associated with the smallest banks, we focus on banks with assets greater than $1 billion. Table I reveals a high degree of homogeneity in the amount of deposit funding. The average bank finances 76% of its assets with deposits. A bank at the 90th percentile in terms of the distribution is 89% deposit-financed, only a bit more than a bank at the 10th percentile which is 74% deposit-financed. A similar pattern holds in the time series for the banking industry as a whole. Figure 1 shows the evolution of the aggregate balance sheets of US banks from 1896 to 2012. As shown in Panel A, banks’ liability structures have been very stable over the past 115 years. Deposits have financed 80% of bank assets on average with an annual standard deviation of just 8%.

These patterns are in sharp contrast to those for non-financial firms, where capital structure tends to be far less determinate, both within industries and over time. This suggests that for banks—unlike non-financials, and counter to the spirit of Modigliani and Miller (1958)—an important part of their economic value creation takes place on the liability side of the balance sheet, via deposit-taking. This is broadly consistent with the literature that has followed Gorton and Pennacchi (1990).

B. Fact 2: Bank assets are more heterogeneous

There is considerably more heterogeneity on the asset side of bank balance sheets, and in particular in their mix of loans and securities. In the 2012 cross-section, a bank at the 10th percentile of the distribution had a ratio of securities to assets of 6.9%, while for a bank at the 90th percentile
the ratio was almost six times higher, at 40.7%. One interpretation of this heterogeneity is as follows: while lending is obviously very important for a majority of banks, a bank’s scale need not be pinned down by the nature of its lending opportunities. Rather, in some cases, it seems that a bank’s size is determined by its deposit franchise, and that taking deposits as given, its problem becomes one of how to best invest them. Again, this liability-centric perspective is very different from how we are used to thinking about non-financial firms, whose scale is almost always presumed to be driven by their opportunities on the asset side of the balance sheet.

C. Fact 3: Bank securities portfolios do not seem to be precautionary liquidity buffers

While banks are quite heterogeneous in their loan and securities mix, within the category of securities banks appear to have relatively well-defined preferences. As can be seen in Table I and Panel A of Figure 2, banks hold very little in the way of Treasury and agency securities: these two categories accounted for just 7.7% and 5.8% of total securities holdings on a value-weighted basis in 2012. The bulk of their holdings are in agency mortgage-backed securities (MBS) and other types of mortgage-linked securities such as collateralized mortgage obligations (CMOs) and commercial mortgage-backed securities (CMBS): these collectively accounted for 57.7% of securities holdings in 2012. Also important is the “other” category, which includes corporate and municipal bonds, as well as asset-backed securities, and which accounted for 29.3% of holdings in 2012.

This composition of banks’ securities portfolios is not what one would expect if banks were simply holding securities as a highly liquid buffer stock against unexpected deposit outflows or loan commitment drawdowns. It also appears—superficially, at least—at odds with the narrow-banking premise that one can profitably exploit a deposit franchise simply by taking deposits and parking them in T-bills. Rather, it looks as if banks are purposefully taking on some mix of duration, credit and prepayment exposure in order to earn a spread relative to T-bills. And indeed, over the period 1984 to 2012, the average spread on banks’ securities portfolio relative to bills is 1.73%.

In this vein, it is interesting to ask how profitable banks would be in a counterfactual world in which their deposit-taking behavior was exactly the same, but instead of allocating their securities holdings as they actually do, they followed a narrow-banking strategy of investing only in T-bills. The profitability of a narrow bank that takes deposits \( DEP \) at a rate \( R_{DEP} \) and invests them in T-bills paying \( R_F \), while incurring deposit-related noninterest expenses of \( NONINTEXP \) (e.g.,

---

4 These figures on securities holdings do not include banks’ holdings of cash and reverse repo, which averaged 10.2% and 4.1% of assets on a value-weighted basis in 2012.
employee salaries, bricks-and-mortar expenses associated with bank branches, and other operating expenses), and earning deposit-related noninterest income of NONINTINC (e.g., services charges on deposit accounts) is given by

$$\Pi = (R_F - R_{DEP}) + \frac{\text{NONINTINC}}{\text{DEP}} - \frac{\text{NONINTEXP}}{\text{DEP}}.$$  \hspace{1cm} (1)

We carry out this calculation for the aggregate commercial banking industry from 1984-2012. To compute the gross deposit spread, $R_F - R_{DEP}$, we use the rate on 3-month Treasury bills as our proxy for $R_F$ and compute $R_{DEP}$ from Call Reports as the interest paid on deposits divided by deposits. Deposit rates appear to embed a significant convenience premium relative to short-term market rates, as the gross deposit spread averages 0.87% over our 29 year sample. We next add the noninterest income that banks earn from service charges on deposit accounts from Call Reports. This averages 0.49% of deposits over our sample. Finally, we subtract the non-interest expense associated with deposit-taking. This is not directly available from Call Reports: banks report their total noninterest expense, but we are only interested in that portion attributable to deposit-taking. As detailed in the Appendix, we use a hedonic-regression approach to infer the expenses associated with deposit-taking. Although these expenses have trended down due to advances in information technology, they remain substantial, averaging 1.30% of deposits over the past 29 years.

Combining these pieces as in equation (1), we estimate the average profitability of narrow banking between 1984 and 2012 to be 0.06% of deposits (0.06% = 0.87% + 0.49% – 1.30%). In other words, the interest rate differential between deposits and short-term marketable rates and the associated fee income is largely offset by the direct costs of operating a deposit-taking franchise. Given these numbers, it is perhaps not surprising that banks choose to invest in riskier securities that earn a spread relative to T-bills. Of course, the large costs of deposit-taking that we document ultimately represent an endogenous choice for traditional banks, and so must be explained as an equilibrium outcome in any fully satisfactory model. For example, banks could always choose to hold down costs by offering fewer physical branch services to their customers, similarly to money-market mutual funds. We return to the endogeneity of deposit-taking expenses below.

\hspace{1cm} 5 In 2012, banks had non-interest operating expenses equal to 2.96% of total assets. These can be decomposed into wage and salary expenses of 1.32%, building occupancy expenses of 0.32%, and other expenses of 1.32%.

\hspace{1cm} 6 This 0.06% figure is probably an upper bound on the profitability of narrow banking. As explained in the Appendix, our methodology for attributing bank expenses to different activities leaves an unallocated cost, which can be thought of as fixed overhead. This overhead cost averages 0.63% of deposits from 1984-2012. If 50% of this amount is allocated back to deposit-taking, the estimated profitability of narrow banking drops to -0.25%.
D. Discussion

Our synthesis of these stylized facts is that traditional banks are in the business of taking deposits and investing these deposits in fixed-income assets that have certain well-defined risk and liquidity attributes, but which can be either loans or securities. The information-intensive nature of traditional lending—in the Diamond (1984) delegated monitoring sense—while clearly important in many cases, may not be the defining feature of banking. Rather, the defining feature may be that, whether they are information-intensive loans, or relatively transparent securities, banks seek to invest in fixed-income assets that have some degree of price volatility and illiquidity, and so offer a higher return than very liquid and safe Treasury securities. In this sense, small business loans, asset-backed securities, and CMOs are on one side of the fence, and Treasuries on the other.

Before proceeding, we should address a natural first reaction to this interpretation. Perhaps banks’ propensity to invest in risky securities merely reflects the fact that they are taking advantage of the put option created by deposit insurance. The evidence we have assembled on the patterns of banks’ securities holdings may just reflect a moral hazard problem, and nothing more.

One way to address this hypothesis is to redo the analysis in Panel A of Figure 2, restricting the sample to those banks with the highest levels of capital at any point in time—those above the median of the distribution by the ratio of equity to assets. This is done in Panel B of Figure 2. The basic patterns for highly capitalized banks in Panel B are very similar to those in Panel A for all banks. Given that these highly capitalized banks are less likely to impose losses on the deposit-insurance fund, we suspect that there is something deeper here than can be explained by a simple appeal to deposit-insurance-induced moral hazard.

III. Model

We develop a simple model in which banks and shadow banks compete as buyers of assets with different degrees of fundamental and liquidity risk. By raising expensive equity capital and gaining access to government deposit insurance, traditional banks obtain stable funding and are able to avoid asset fire sales. As a result, traditional banks can create money-like claims by patiently investing in illiquid fixed-income assets, which are safe in the long run but vulnerable to short-term price volatility. Shadow banks have less expensive funding, but are vulnerable to runs and early asset liquidations. While their reliance on early exit means that shadow banks can create money-like claims by investing in assets with higher fundamental risk, these assets must be more liquid.
Although we use the terms “traditional bank” and “shadow bank” as a short-hand, we emphasize that the model speaks to intermediation strategies as opposed to specific legal institutions.

A. Setting

The basic structure of the model is similar to Stein (2012). The model has three dates, \( t = 0, 1 \) and 2. There are \( N \) long-lived risky assets indexed by \( i = 1, 2, \ldots, N \). Asset \( i \) is available in a fixed supply of \( Q_i \). For simplicity, we assume that the payoffs on these assets are perfectly correlated, and assets only differ in the magnitudes of these payoffs in the bad state of the world. The individual assets in our model might correspond to corporate loans, mortgages, mortgage-backed securities (MBS), US Treasuries, or even equities.

The model features three types of actors: households, traditional banks, and shadow banks. Households do not directly own any of the risky assets. Instead, households invest in safe and risky claims issued by traditional and shadow banks, which in turn back these claims by holding the underlying risky assets. Intermediation is efficient here because households are willing to pay a premium for completely safe claims, and some form of intermediation is required to create safety—none of the primitive assets are themselves safe.

Outside of this demand for safe money-like claims, households are assumed to be risk neutral. In other words, once a claim has any risk at all, the discount rate applied by households is fixed at a discretely higher level. This corresponds to the following household utility function, taken from Stein (2012)

\[
U = C_0 + \beta E[C_2] + \gamma M,
\]

where the notational convention is that a household has \( M \) dollars of money-like claims if it has claims that are guaranteed to pay off an amount \( M \) at \( t = 2 \). The discount factor applied to all risky claims is thus \( \beta \leq 1 \) while the discount factor applied to safe, money-like claims is \( \beta + \gamma \) where \( \gamma \geq 0 \). The former follows from the observation that a household is indifferent between having \( \beta \) units of time-0 consumption and a risky claim that delivers one unit of time-2 consumption in expectation. The latter follows from the fact that a household is indifferent between having \( \beta + \gamma \) units of time-0 consumption and a riskless claim that always delivers one unit of time-2 consumption. Such a claim delivers \( \beta \) units of utility from expected future consumption, along with additional \( \gamma \) units of utility in current monetary services.

When \( \gamma > 0 \), the discount rate applied to safe, money-like claims, \( 1/(\beta + \gamma) \), is less than the discount rate applied to risky claims, \( 1/\beta \). As in Stein (2012), Gennaioli et al. (2013), and DeAngelo
and Stulz (2014), the assumptions of the Modigliani-Miller (1958) theorem no longer hold and the value of a risky asset may depend on the way it is financed using safe and risky claims.\(^7\)

The timing of the model is as follows. Each risky asset \(i\) pays \(R\) at \(t = 2\) if the aggregate economic state of the world is good, but a lower amount \(z_i < R\) if the aggregate economic state at \(t = 2\) is bad. In addition, there is a very small probability of an economic disaster in which case all risky assets pay 0. At time 1, there is an interim news event about the future economic state. With probability \(p\), the interim news is optimistic, which means that the aggregate state will be good at time 2 and all assets will definitely pay \(R\). With probability \((1–p)\), the news is pessimistic, which means that there is a subsequent probability of \(\varepsilon\) of the disaster state in which there is a zero payoff on all risky assets at time 2 and a \((1–q–\varepsilon)\) probability of the bad state and low payoff on all assets.

Thus, after pessimistic news at time 1, the fundamental value of asset \(i\) is \(F_i = qR + (1–q–\varepsilon)z_i\).

The small probability of an economic disaster—the existence of tail risk—means that it is impossible to raise uninsured funding that is both stable and completely safe. In other words, intermediaries can only manufacture safe claims by either relying on an early exit option, in which case the resulting funding is unstable, or on deposit insurance, in which case it is stable. Thus, our

---

\(^7\) The assumption that all money-like claims are perfect substitutes is a simplification. Krishnamurthy and Vissing-Jorgensen (2013) and Sunderam (2014) explore imperfect substitutability between different money-like claims.
assumption that $\varepsilon > 0$ is a simple way of capturing the robust fact that intermediaries who rely heavily on short-term, uninsured funding have always been vulnerable to run-like withdrawals when bad news arrives. Of course, if $\varepsilon = 0$, it would be possible to raise stable, funding without deposit insurance, simply by limiting the amount of short-term claims to the worst-case payoff, $z_i$. And, indeed, all of our formal results carry through in the special case where $\varepsilon = 0$. However, in this case, the quantity of stable deposits would be limited by asset payoffs in the worst possible scenario.

Our central assumption deals with the difference between the fundamental value of asset $i$ at time 1, and its market value. We assume that, if there is pessimistic news at time 1, the market value of asset $i$ is $k_iF_i \leq F_i$. When $k_i < 1$, this market price reflects a fire-sale discount to fundamental value. The value of $k_i$ is endogenous and asset-specific and depends on the equilibrium quantity of asset $i$ that is liquidated at time 1. We return to this feature momentarily.

Because our model only features aggregate risk and the payoffs on all assets are perfectly correlated, we are abstracting away from the need for diversification and risk management which DeAngelo and Stulz (2014) argue are central to intermediaries’ ability to produce safe money-like claims. Our approach can be thought of as reflecting the idea that intermediaries have already done the best they can on these diversification and risk-management fronts, leaving only aggregate risk that cannot be diversified away or hedged.

B. Intermediation strategies

To examine the different ways the risky assets can be held and used as backing to create safe claims, we consider two intermediation strategies: stable traditional banking and unstable shadow banking. At $t = 0$, households can invest in either traditional or shadow bank deposits, both of which are completely safe and are valued at $\beta + \gamma$ per dollar paid at $t = 2$. Alternatively, households can buy bank equity or shadow bank equity, both of which are risky and are valued at $\beta$ per dollar paid in expectation at $t = 2$. Fraction $\mu_i$ of risky asset $i$ is purchased by shadow banks at $t = 0$ and fraction $1 - \mu_i$ is purchased by traditional banks. We examine how the equilibrium market shares of the traditional and shadow banking strategies vary as we change the properties of the asset in question.

B.1. Traditional banking

The traditional banking strategy uses deposit insurance and a hold-to-maturity investment approach to back safe short-term claims. A combination of risk-based capital requirements and fairly priced deposit insurance prevents traditional banks from exploiting the deposit insurance fund. Specifically, we assume that the government offers traditional banks actuarially fair deposit
insurance that pays off in the disaster state. With a small probability of an economic disaster, traditional banks’ hold-to-maturity strategy can only be used to create safe claims if it is combined with deposit insurance. To protect taxpayers from further exposure, the government imposes a particular form of risk-based capital regulation: the bank is required to hold enough capital against any asset \( i \) such that the deposit insurer never suffers losses in equilibrium in the bad (as opposed to the disaster) state. Since the bank plans to always hold the risky asset to maturity, the maximum amount of insured money-like claims that can be created using asset \( i \) under this regulatory regime is \( z_i \), which is the payoff in the bad state at time 2. To satisfy the risk-based capital rule, the remainder of the asset purchase must be financed by risky equity capital which is more expensive. Since the disaster state occurs with probability \((1-p)\varepsilon\) and deposit insurance pays \( z_i \) in this state, the actuarially fair insurance premium discounted back to time 0 is \((1-p)\varepsilon\beta z_i\).

In the literal context of the model, capital regulation and the deposit insurance premium are the only costs to being a deposit-insured bank with stable funding, as opposed to a shadow bank with unstable funding. More broadly, however, one might interpret what we are calling the cost of equity capital as encompassing a variety of other costs that go along with being a traditional bank. These include the costs of other types of regulation, as well as the bricks-and-mortar costs of setting up the sort of branch network that attracts retail depositors.

The total value of claims the bank can issue at time 0 using the risky asset \( i \) as backing is

\[
V_i^B = \frac{\text{Value of bank deposits}}{\text{Money premium}} - \frac{\text{Insurance premium}}{\text{Expected cash flows}} - \frac{\text{Value of bank equity}}{\text{Money premium}} + \beta(p + (1-p)q)(R - z_i)
\]

(3)

where, again, \( F_i = qR + (1-q-\varepsilon)z_i \) is the fundamental value of asset \( i \) following pessimistic news at time 1. In any equilibrium where banks hold asset \( i \), banks’ zero profit condition ensures that the market value of asset \( i \) equals \( V_i^B \). Because households are willing to pay a premium for absolutely safe claims, equation (3) shows that the total value of claims issued by banks exceeds the expected cash flows on the risky asset discounted at the risky rate: banks capture a money premium of \( \gamma z_i \) because deposit insurance enables them to use the risky asset to back \( z_i \) units of safe claims.

**B.2. Shadow banking**

An alternative intermediation strategy for creating safe money-like claims is shadow banking. In the real world, what we are calling the shadow banking strategy often involves a chain of market-based transactions which can involve several distinct legal institutions.
Perhaps the simplest of these institutions is a money market fund (MMF) that invests in assets that are completely riskless such as Treasury bills and issues what are effectively deposits to households. Things become more complex when the asset ultimately backing the MMF deposits is not completely risk-free. To ensure that the MMF deposits are truly safe, some institution along the intermediation chain must contribute financing in the form of equity capital. At the end of the chain, households own a combination of money-like MMF deposits and highly-levered equity.

This shadow banking strategy can be implemented using several alternative institutional arrangements, with more or fewer links in the chain. For example, a mortgage-backed security (MBS) may ultimately wind up backing money-like claims in several ways:

- A broker-dealer affiliate of a universal commercial bank finances the MBS using its own equity and a short-term repurchase agreement with a money market fund.
- A hedge fund acquires the MBS using its own equity and an overnight collateralized loan—a bilateral repo—from its prime broker. The prime broker in turn uses the same collateral to borrow from a money fund in the tri-party repo market, a process called “rehypothecation.”
- A structured investment vehicle finances the MBS using its own equity and asset-backed commercial paper that is then sold to a money market fund or an institutional cash manager.

In each case, the common denominator is that there is a short-term claim at the end of the chain that is “flighty”—i.e., vulnerable to withdrawal in a bad state—because it is uninsured and is protected only by the ability to exit early and liquidate the underlying collateral.

To fix ideas, it may be helpful to think of a simplified two-step chain consisting of a highly-leveraged intermediary (HL) such as a broker-dealer along with a money market fund (MMF). The HL buys the risky asset, and issues short-term repo against it, which is then held by the MMF. MMF deposits and HL equity are owned by households. The MMF does not have capital or access to government deposit insurance, so for its deposits to be riskless its repo holdings must also be riskless. This is the case because, if there is pessimistic news at time 1, the MMF seizes the repo collateral and sells it at the fire-sale price of $k_iF_i$. The maximum amount of safe money that can be created by a shadow bank is therefore $k_iF_i$. Unlike traditional bank depositors protected by deposit insurance and bank equity capital, an MMF that invests in repo cannot afford to sleep through time 1; the MMF’s ability to pull the plug at this interim date is essential to keeping its claim safe.
Uninsured shadow banking deposits are therefore an endogenous form of “hot” money: they are unstable rather than stable short-term funding.\textsuperscript{8}

The total value of claims the shadow banking system can create using the risky asset \(i\) as a backing is then given by

\[
V^S_i(k_i) = (\gamma + \beta)k_iF_i + \beta p(R - k_iF_i) = \gamma k_iF_i + \beta[pR + (1 - p)k_iF_i].
\]  \(\text{(4)}\)

In any equilibrium where shadow banks hold asset \(i\), their zero profit condition ensures that the market value of asset \(i\) must equal \(V^S_i(k_i)\).

C. Equilibrium

We assume that shadow banks face a downward-sloping demand curve at time 1, so the fire-sale price is a decreasing function of the amount of the asset that is liquidated. Formally, let \(0 \leq \varphi_i\) be an exogenous parameter that indexes the illiquidity in the secondary market. We assume that \(\partial k(\mu, \varphi_i)/\partial \mu \leq 0\), so demand is downward sloping, and \(\partial^2 k(\mu, \varphi_i)/\partial \mu \partial \varphi_i \leq 0\), so more illiquid assets have steeper demand curves. Finally, as a normalization, we assume that \(k(\mu_i, 0) = 1\) for all \(\mu_i\): when \(\varphi_i = 0\), the asset is perfectly liquid and there is never any fire-sale discount. As shown in the Appendix, a fire-sale discount of this form can be micro-founded as in Stein (2012).\textsuperscript{9}

Since intermediaries are risk-neutral and there are no benefits of diversification built into our model, intermediaries’ willingness to hold asset \(i\) is not impacted by their holdings of asset \(j \neq i\). As a consequence, market equilibrium in any asset \(i\) naturally decouples from that in asset \(j \neq i\). An equilibrium for asset \(i\) is a \(\mu_i^*\) such that

\[\text{Households only derive monetary services from claims that are guaranteed to be a safe store of value through time 2. For uninsured shadow banks, safety requires early exit and hence a fire sale if the bad state occurs at time 1. However, ex post, the expected value is higher, albeit riskier, if the assets are held to maturity. So what ensures that the assets will be sold, thereby making good on the promise of safety? For some shadow-banking chains, there may be coordination problems that lead to runs and hence force fire sales. However, even in the absence of coordination problems—e.g., if each MMF that invests in repo is protected by a segregated piece of collateral—commitment technologies can force the sale. For instance, MMFs are prohibited from holding the long-term assets that serve as collateral for repos, which pre-commits them to a policy of fire-selling this collateral. While this commitment may lead to inefficiencies ex post, it is optimal for MMFs ex ante, as it helps to assure their investors that their claims will be kept safe.}

\[\text{Specifically, we assume that the risky asset is sold to a third type of intermediary (also owned by households) who has fixed resources and access to outside investment opportunities at } t = 1. \text{ Since these opportunities are characterized by diminishing returns, shadow banks must offer larger discounts to induce these intermediaries to purchase more assets, thereby foregoing increasingly productive outside opportunities. In this context, differences across assets in } \varphi_i \text{ reflect differences in the number of potential second-best holders of each asset—i.e., differences in asset specificity.}\]
The model admits both interior outcomes and corner solutions, depending on the asset-specific values of $z_i$ and $\phi_i$. It is consistent with the possibility that some assets (e.g., highly illiquid loans) are held only by banks, some (e.g., Treasuries) are held predominantly by shadow banks, and some (e.g., MBS) are held in significant amounts by both intermediary types.

Formally, since $V_i^B = V_i^S(k(\mu^*_i, \phi_i))$ for $\mu^*_i \in (0, 1)$, $V_i^B > V_i^S(k(0, \phi_i)) \Rightarrow \mu^*_i = 0$ and $V_i^B < V_i^S(k(1, \phi_i)) \Rightarrow \mu^*_i = 1$.\(^{(5)}\)

Since shadow banks dominate traditional banks when there is no fire-sale discount (i.e., we always have $V_i^B < V_i^S(1)$), we only have a corner equilibrium where the assets is held entirely by traditional banks when $k(0, \phi_i) < 1$. By contrast, if $k(0, \phi_i) = 1$, then shadow banks must always hold some of the asset in equilibrium.

At an interior equilibrium where both traditional and shadow banks hold the asset, the fire-sale discount $k_i$ is such that both traditional and shadow banks earn zero profits by buying the asset and issuing claims backed by it. Thus, at an interior equilibrium,

$$\beta \times \left[1 - k(\mu^*_i, \phi_i)\right] \times F_i = \gamma \times \left[k(\mu^*_i, \phi_i) \times F_i - z_i\right].$$

Equation (6) says that the mix between shadow banks and traditional banks must be such that marginal benefit of stable bank funding equals the marginal cost of stable funding. Stable funding allows traditional banks to avoid the fire-sale liquidation discount if there is pessimistic news at time 1. This benefit of traditional banks relative to shadow banks is captured by the left-hand-side of (6). However, precisely because investors can get out early, the market can generate a larger amount of unstable short-term funding than of stable funding using a given asset as backing. This cost of traditional banking relative to shadow banks is captured by the right-hand-side of (6). In summary, although traditional banks have more stable funding than shadow banks, this stability comes at a price: traditional banks create fewer money-like claims than shadow banks.

Solving equation (6), the equilibrium fire-sale discount is

\(^{(10)}\) Implicitly, by requiring $\mu \in [0, 1]$, we are imposing a short-sale constraint for both traditional and shadow banks.
Finally, inverting the \( k(\mu, \varphi) \) function, the equilibrium fraction of asset \( i \) held by shadow banks is\(^{11} \)

\[
\mu_i^* = k_i^{-1}\left( \frac{\gamma z_i + \beta(1-p)F_i}{\gamma F_i + \beta(1-p)F_i} \right).
\]  

(8)

To take a simple parametric example, assume \( k(\mu, \varphi) = 1 - \varphi \mu \). In this case, we have \( \mu_i^* = 1 \) if \( \varphi_i = 0 \)—i.e., the asset is held exclusively by shadow banks if there is no fire-sale discount—and

\[
\mu_i^* = \min\left\{ \frac{1 - k_i^*}{\varphi_i}, 1 \right\} = \min\left\{ \frac{1}{\varphi_i} \frac{\gamma(F_i - z_i)}{\gamma F_i + \beta(1-p)F_i}, 1 \right\},
\]  

(9)

if \( \varphi_i > 0 \), so that \( \mu_i^* \to 0 \) as \( \varphi_i \to \infty \).

The equilibrium in our model is in the spirit of Miller (1977). While the aggregate mix of unstable (\( \mu_i \)) versus stable funding (1–\( \mu_i \)) for each asset \( i \) is pinned down, so long as we are in an interior equilibrium, any small intermediary is indifferent between setting up shop as a bank or as a shadow bank. Relatedly, the model is silent about the boundaries of financial firms. In particular, it is possible that a single institution—e.g., a universal-style bank with a broker-dealer affiliate—winds up using both the traditional and shadow banking strategies.

Equation (6) says that the equilibrium fire-sale discount is locally independent of asset illiquidity \( \varphi_i \) at an interior equilibrium where both traditional and shadow banks hold the asset. In this region, a change in asset illiquidity impacts the mix of asset holders—an increase in illiquidity raises the market share of banks—but leaves the fire-sale discount unchanged. However, if the assets are sufficiently liquid (\( \varphi_i \) is very low), the market share of traditional banks is eventually driven to zero, so the fire-sale discount is increasing in asset illiquidity for very low levels of \( \varphi_i \).

D. Comparative statics

This simple model can be used to characterize the kinds of assets for which the traditional banking model dominates. Two factors drive the tradeoff between traditional banks and shadow banks: the money premium for safe claims which is controlled by \( \gamma \) and the strength of the fire-sale effect which is controlled by \( \varphi_i \).

\(^{11}\) Formally, the function \( k_i^{-1}(x) \) is implicitly defined by \( x = k(k_i^{-1}(x), \varphi_i) \).
First, if \( \gamma = 0 \) and \( \partial k(\mu_i, \varphi_i) / \partial \mu_i < 0 \), we have \( \mu^*_i = 0 \)—the risky asset is held entirely by traditional banks. If there is no premium for safe claims, shadow banking is dominated by traditional banking: unstable short-term debt forces inefficient liquidations and has no offsetting monetary benefits relative to stable deposit funding.

Conversely, if \( \gamma > 0 \) and \( \varphi_i = 0 \) so that \( k(\mu_i,0)=1 \) for all \( \mu_i \), then \( \mu^*_i = 1 \)—the asset is held entirely by shadow banks. The entire advantage of traditional banks’ stable funding is that it enables them to ride out temporary departures of price from fundamental value without liquidating assets. If there is no fire-sale risk and the price at time 1 always equals fundamental value, then stable funding has no value; however, when \( \gamma > 0 \), raising stable funding is always more costly than raising unstable funding.

The ideal asset for a traditional bank is one that has very little fundamental cash-flow risk (i.e., \( z_i \) is high so risk-based capital rules allow a bank to use it to back a lot of money-like deposits), but that is exposed to meaningful interim price re-pricing risk (i.e., \( \varphi_i \) is high so fire-sale risk looms large for its shadow-bank counterparts). When both \( \gamma > 0 \) and \( \varphi_i > 0 \), there is a meaningful trade-off between the two intermediation structures and we will have an interior equilibrium.

For an interior equilibrium, we can ask how the equilibrium market shares of shadow banks \( \mu^*_i \) and traditional banks \( 1 - \mu^*_i \) vary with the exogenous model parameters. Differentiating equation (8), we immediately obtain the following comparative statics for the fraction of an asset held by traditional banks:

1. \( \partial(1-\mu^*_i) / \partial \varphi_i > 0 \): **An increase in asset illiquidity increases the equilibrium share held by traditional banks.** By assumption, an increase in asset illiquidity makes the demand curve for fire-sale liquidations at time 1 steeper. Although a change in asset illiquidity \( \varphi_i \) has no effect on the equilibrium level of the fire-sale discount in (7), this change alters the mapping between the ownership mix and the fire-sale discount in (8). When \( \varphi_i \) is high, the fire-sale discount is highly sensitive to the volume of forced sales by shadow banks, so traditional banks end up holding more of the asset in equilibrium.

2. \( \partial(1-\mu^*_i) / \partial z_i > 0 \): **An increase in the worst-case cash flow \( z_i \) increases the share of the risky asset \( i \) held by traditional banks in equilibrium.** An increase in \( z_i \) reduces the money-creation advantage of shadow banks relative to traditional banks, and therefore needs to be
compensated by a rise in $k_i^*$ which implies a rise in $1 - \mu_i^*$ to restore equilibrium indifference between traditional and shadow banks. We think of a higher $z_i$ as being associated with less fundamental cash-flow risk. Thus, all else equal, traditional banks have a comparative advantage at holding assets with little fundamental cash-flow risk.

Taken together, these two results suggest that traditional banks have a comparative advantage at holding illiquid fixed income assets—i.e., assets that may experience significant temporary price dislocations, but at the same time, have only modest fundamental risk. Agency MBS might be a leading example of such an asset, since they are insured against default risk, but are considerably less liquid than Treasury securities, and for a given duration, have more price volatility, since there is significant variability in the MBS-Treasury spread.

The model also explains why banks are not well-suited to investing in equities—equities simply have too much fundamental downside risk. Because their value can fall very far over an extended period of time—i.e., because their $z_i$ is close to zero—equities cannot be efficiently used as backing for safe two-period claims. One reflection of this fact is that when banks do hold equities, they face prohibitively high regulatory capital requirements. In contrast, to the extent that they are highly liquid, equities do make suitable collateral for very short-term repo financing and can be used to back some amount of shadow-bank money.

What happens as the underlying asset grows increasingly safe and liquid, itself becoming nearly money-like? In practice, this corresponds to asking who will hold short-term Treasury bills. In this limiting case, both the benefits and the costs in equation (6) vanish, so in our model the mix between traditional and shadow banks is indeterminate. However, this mix would be pinned down if we introduced a small overhead cost of traditional banking that scaled with assets under management, such as a cost of regulatory compliance. In this case, we would expect a non-bank vehicle such as a money market fund to hold the vast majority of T-bills.

In addition, we have the following comparative statics which impact all assets:

3. $\partial(1 - \mu_i^*)/\partial \gamma < 0$: An increase in the money premium on safe claims lowers traditional banks’ equilibrium market share of all risky assets. When the premium associated with

---

12 U.S. banks are currently required to finance any common stock holdings with at least 24% of loss-absorbing capital. The corresponding capital requirements for commercial loans and residential mortgages are 8% and 4%, respectively.
safe money-like claims is higher, the fire-sale discount must rise to maintain equilibrium (i.e., \( k^i \) must fall), so the fraction of risky assets held by shadow banks, \( \mu^i \), must rise.

4. \( \partial (1 - \mu^i) / \partial p < 0 \): **An increase in the probability of good news at time 1 lowers the share of all risky assets held by traditional banks.** When the interim good state is more likely, a larger fire-sale discount (lower \( k^i \)) is needed to restore indifference and the market share of shadow banks, \( \mu^i \), must rise in equilibrium. Intuitively, bank’s stable funding structure functions as a costly form of insurance against fire-sale risk; this insurance naturally becomes less valuable when a fire sale is less likely (i.e., when \( p \) rises).

Comparative static #3 suggests that an increase in the demand for safe, money-like assets should trigger a migration of intermediation from traditional to shadow banking. Indeed, some observers have argued that such an increase in money demand played a role in fueling the rapid growth of shadow banking prior to the recent financial crisis.\(^{13}\) Comparative static #4 suggests that intermediation activity tends to migrate away from traditional banks and towards shadow banks during economic expansions when \( p \) is high. In this way, our model provides a way of understanding why traditional banks lost significant market share to shadow banks during the run-up to the recent financial crisis.

**E. Model extensions**

We have deliberately kept the model quite spare. First, we have assumed that the demand for safe claims is infinitely elastic and hence never satiated (i.e., households have linear utility over safe asset holdings). In a more general model, the demand for safe claims would be downward-sloping (corresponding to concave utility over safe claims), so the liquidity premium would decline with the total quantity of safe claims provided by intermediaries. We can extend our model to allow the liquidity premium to be determined this way in equilibrium. Holding fixed the equilibrium money premium, our key results on the cross-section of risky assets still obtain: traditional banks hold a larger share of more illiquid assets and of assets with less fundamental risk.

We have also implicitly assumed that, to the extent it is technologically feasible, intermediaries use all risky assets as fodder for backing money-like claims. One might extend the

---

model so that some risky assets are not used to back money-like claims and instead are held directly by households in equilibrium. For some risky assets to not be used as fodder for backing safe claims, we would need to add an overhead cost of traditional banking—perhaps a cost that is increasing in traditional banks’ market share as in DeAngelo and Stulz (2014). Going further, we could add assets like Treasury bills that are perfectly safe even in the absence of any tranching by financial intermediaries. As explored in Greenwood, Hanson, and Stein (2015) and Krishnamurthy and Vissing-Jorgensen (2015), with downward-sloping demand for money-like assets, changes in the supply of T-bills would depress the premium on safe claims, reducing the incentive of shadow banks and traditional banks to bear the fire-sale and overhead costs incurred in intermediation.

F. Discussion

While banks’ asset holdings are the most noteworthy complement to their stable funding structures, our model may help shed light on other aspects of commercial banks’ modern business model. Consider for example the bricks-and-mortar costs associated with bank deposit-taking. We have estimated these costs to be quite high, averaging on the order of 1.30 percent of deposits over the period from 1984 to 2012. These costs ultimately represent a choice—banks could always choose to offer their customers fewer and less attractive branch locations, fewer opportunities for interacting with a human teller, and so forth. One view is that these amenities are simply a separable flow of services to depositors, conceptually analogous to paying more interest. However, an interesting alternative is that they represent a deliberate effort to build loyalty by creating a form of switching costs. Investing in switching costs in this way, and thereby further increasing deposit stickiness, would naturally be complementary to an overall business model based on the premise of having stable funding. By contrast, a money market fund complex—which also takes deposits, but which invests exclusively in short-term assets—has less reason to care about deposit stickiness, and hence less incentive to spend as heavily on a branch network.

The model may also have something to say about the contrasting accounting practices of commercial banks and the institutions that play a crucial role in the shadow banking system: money market funds, broker-dealers, and hedge funds. These market-based institutions typically lack access to stable short-term funding and operate on a mark-to-market accounting basis. Even if a decline in security prices is temporary and driven by non-fundamental factors, it impacts their accounting earnings. In contrast, accounting conventions for banks shield their earnings from transitory changes in the unrealized market value of loans or securities. These “temporary impairments” flow through another liability account called “accumulated other comprehensive
income” and only impact reported earnings if the gains or losses are realized by selling the security. If movements in asset prices are driven entirely by fundamental news about future cash flows, then commercial banks’ accounting practices seem perplexing. However, to the extent that asset price movements are driven by non-fundamental shocks which the banks’ stable funding structure enables them to ride out, these accounting practices may be sensible (see also Cochrane 2011).

IV. Commercial Banks in Historical Perspective

Our model may shed light on the changes in the commercial banking model in the U.S. over the last 150 years. Our central prediction is the complementarity between the three features of modern commercial banking: deposit insurance, stable funding, and investment in long-term fixed-income assets that are nonetheless subject to price fluctuations. It is therefore natural to ask what commercial banking in the U.S. looked like before the introduction of deposit insurance. The model predicts, not surprisingly, that bank funding was less stable. Perhaps more surprisingly, the model also predicts that bank assets prior to deposit insurance would have needed to be shorter-term and easier to liquidate without losses. The evidence presented below is strikingly consistent with this prediction. Indeed, during the late 19th and early 20th centuries, U.S. commercial banks employed a business model similar to the strategy we have called “shadow banking.”

During the National Banking Era from 1865–1914, nationally-chartered banks were financed with demand deposits (68% on average during this period), national bank notes (8%), and equity (24%). While commercial banks were heavily reliant on deposit funding just as they are today, they held very different assets.14 Because without deposit insurance the banking system regularly faced mass withdrawals by depositors, the prevailing banking philosophy—enshrined in both the National Banking Act of 1864 and the Federal Reserve Act of 1913—“emphasized the importance of keeping bank assets liquid by (largely) confining the use of bank funds to short-term loans” (Moulton 1919, p. 638).

To begin, national banks held far more cash and interbank deposits than they do today. On average, cash items accounted for 27% of assets from 1865–1914 versus less than 4% for commercial banks prior to the 2008–2009 crisis.15 Banks’ loan portfolios (averaging 55% of assets)

---

14 National bank notes—a form of legal paper money backed by banks’ holdings of certain U.S. Treasury securities—were a major liability item for national banks during the beginning of the era.

15 Legal reserve requirements were far higher—reserve requirements on all deposits were 15% for country banks and 25% for city banks. Today reserve requirements are 10% on transaction accounts, which account for only 12% of total
were concentrated in short-term loans to finance working capital or short-term collateralized loans. Summarizing the era’s lending philosophy, Kniffin explained (1915, p. 209), “the secret of sound banking is to have a steady stream of money coming in by way of maturing loans, so the … demands of the checking depositors may be met.” Finally, from 1865–1914, securities comprised 17% of bank assets. Banks’ securities were concentrated in Treasuries, state and local bonds, and railroad bonds—all “of high grade as to both security and marketability,” (Moulton 1919, p. 711).

Banks primarily made short-term “commercial loans” to finance working capital that were “automatically self-liquidating”, while avoiding illiquid longer term “industrial loans” to finance permanent capital (Myers 1931, White 1998). The Comptroller of the Currency bluntly summarized this view in 1876, stating that “Banks are not loan offices. It is not part of their business to furnish their customers with capital,” (Bolles 1890, p. 70). Prior to 1913, national banks were prohibited from making real-estate loans. According to Pollock (1993) the rationale was that, “deposits payable on demand should not be invested in real estate financing.”

The principal lending instruments included loans secured by short-term trade receivables or “trade acceptances” (similar to factoring), short-term unsecured working capital loans or “commercial paper”, over-night margin loans collateralized by stocks and bonds or “call loans”, and other short-term, collateralized, loans. Of course, banks typically rolled over these short-term loans in normal times (Moulton 1919).

In 1896, 20% all loans by national banks were due on demand, primarily in the form of call loans backed by stocks and bonds (Statistical Abstracts of the U.S., 1896, Table 28). Trade acceptances and commercial paper were also quite short-term. James (1978) argues that the maturities of these loans typically ranged from 30 to 90 days, with an average maturity of 60 days and an upper bound of one year. Furthermore, the banks in major cities—which faced the greatest risk of withdrawal by depositors—tended to hold shorter-term paper than country banks whose deposits were somewhat more sticky (Myers 1931).

Commercial banks’ maturity mismatch and deposits. However, according to Myers (1931), reserve requirements were not binding: most state-chartered banks had voluntarily held similar levels of reserves prior to the passage of the National Banking Act.

The Federal Reserve Act of 1913 loosened this restriction somewhat, allowing national banks to make loans secured by farmland, provided they were limited to a 50% loan-to-value ratio and maturities of less than 5 years. However, real estate loans were limited to the greater of 25% of a bank’s capital or 33% of its time deposits. In 1916, national banks were permitted to make 1-year loans secured by urban real estate. These limits on real estate lending were gradually relaxed and were eliminated with the Garn-St. German Act of 1982.

To ensure they were not financing permanent capital, banks subjected borrowers to an annual “clean up,” requiring them to briefly repay all debts, perhaps by borrowing from another bank (Moulton 1919, White 1998).

For instance, while loans due on demand were 12% of the loan portfolios of country banks, they represented 35% of loans for banks in New York City. (Statistical Abstracts of the U.S., 1896, Table 28).
liquidity mismatch were far more limited than they would become after the introduction of deposit insurance in 1933 (White 1998).

Furthermore, there were telling differences between national banks, which were largely financed with demand deposits, and state banks, which were more reliant on savings and time deposits.\(^{19}\) While state banks also made very short-term commercial loans, they made some longer-term real estate loans. However, under state regulations, the amount of real estate loans was tied to amount of time deposits or equity capital (White 1998). Pollock (1993) summarized the rationale for these regulations, stating that “Real estate loans, which represent, by definition illiquid underlying assets, should be explicitly tied to less liquid bank liabilities.” Finally, there were a set of “mutual savings banks” that specialized in longer-term real estate loans. However, mutual savings banks were entirely financed by equity and retail savings deposits that faced withdrawal limitations.

During the recurring financial crises of this era—there were major banking panics in 1873, 1884, 1893, 1890, 1896, 1907, and 1914 (Calomiris and Gorton 1991)—banks tended to face significant withdrawals from individual depositors. For instance, during the severe panics of 1873 and 1893, deposits at national banks shrank by 16% and 17%, respectively, over the course of several months. These withdrawals were met in part by drawing down excess reserves, but also by calling in loans due on demand and declining to roll over maturing time loans (Sprague 1910, Myers 1931, Friedman and Schwartz 1963). In 1873 and 1893, total loans extended by national banks shrank by 17% and 15%, respectively. Consistent with an inward shift in loan supply, crises were typically marked by large spikes in interest rates—call loan rates often rose by 10 or more than percentage points with commercial paper rates rising by 3 or more percentage points (Sprague 1910, Champ 2007).\(^ {20}\) Since country banks typically drew down balances they held at city banks, these loan “liquidations” were often most pronounced at city banks, particularly New York City banks. In the Panic of 1873, loans extended by New York City banks shrank by 41%.

These loan liquidations were similar to the fire-sale mechanism in our paper. The closest analog lies in the call loans secured by stocks and bonds. The forced sales triggered by reductions in

---

\(^{19}\) In part, this was because national banks faced the same reserve requirement on all deposit types. By contrast, state banks typically faced lower reserve requirements for time and savings deposits (White 1998).

\(^{20}\) The behavior of commercial bank deposits and lending during crisis periods in the late 19th and early 20th centuries stands in sharp contrast to the behavior of today’s insured commercial banks. In more recent times, insured bank deposits have often benefitted from safe-haven inflows during crisis periods. Furthermore, there is often an expansion in outstanding bank loans during periods of financial strain as existing loan commitments are drawn down (Kashyap, Rajan, and Stein 2002, Gatev and Strahan 2006, Scharfstein and Ivashina 2010).
margin lending were widely thought to have exacerbated the declines in stock and bond prices in many of the era’s financial crises, including the 1929 crash (Sprague 1910, Tallman and Moen 1990, Galbraith 1954, and Meltzer 2002). The inevitable post-crisis decline in real activity was often attributed, in part, to the forced liquidation of commercial loans used to finance working capital. Moulton (1919) recognizes the costs of these liquidations, writing (p. 719-720):

“Loans to [meat]packers had always been considered extremely liquid, and when, in 1907, the Chicago banks were desirous of replenishing their reserves they asked Mr. Armour to liquidate his loans ... Now it is true that any particular packing-house note is liquid. It will be paid whenever a bank desires—even before maturity ... But such payments are largely effected through a shifting process, for the loan from bank A that is paid promptly reappears as a loan from bank B ... But while any particular [meat]packing-house loan is thus liquid, it is an entirely different matter when it comes to liquidating all of them at once. Banks ... furnish permanent working capital to the [meat]packers, and it would be impossible for the packing-houses to liquidate all their loans without disrupting the entire live-stock industry.”

Importantly, the ubiquity of short-term bank loans during this era does not appear to stem from a lack of demand for long-term credit. According to Myers (1931, p. 45), “attempts on the part of a bank to confine its loans to short-term paper were often bitterly resented by the community.” To the extent that state governments or corporations (e.g., railroads) needed access to long-term financing, they had to sell stock or bonds (Moulton 1919, White 1998). Stocks and bonds were often bought by foreign investors (Myers 1931) or domestically by life insurers who had long-term sticky liabilities (White 1998). Interestingly, there was a thriving original issue high-yield bond market in the first several decades of the 20th century, many decades before Michael Milken (Greenwood and Hanson 2013). A plausible hypothesis is that the junk bond market flourished precisely because banks were unable to supply longer-term loans to commercial borrowers.

After the introduction of federal deposit insurance in 1933, one of the major policy goals was to encourage banks to make longer-term and effectively more illiquid loans. Specifically, bank regulators were asked not to “criticize” long-term commercial loans and national banks were given much greater latitude to make real estate loans starting in 1934 (White 1998). It appears that policymakers were concerned that the kind of short-term lending that had dominated prior to the introduction of federal deposit insurance had imposed a sort of credit-crunch externality on the real economy, making economy-wide downturns more severe because firms were forced to prematurely liquidate real projects to pay-off short-term bank loans.

In summary, in the late 19th and early 20th centuries, the deposits of U.S. commercial banks were kept safe and liquid by largely restricting bank assets to cash and very short-term loans—i.e.,
by limiting the liquidity mismatch between assets and liabilities. What we have termed the “traditional banking” strategy—a buy-and-hold approach that uses long-term, illiquid assets to back short-term deposits—is best seen a mid-20th century development that was made possible by the introduction of a reliable lender of last resort and federal deposit insurance.

V. Contemporary Evidence

In this section, we provide some contemporary aggregate evidence bearing on the model’s predictions. We think of this analysis more as a synthesis of known high-level facts about the structure of financial intermediation than as a true test of the model. We first describe how we take the model to the data, then our measurement approach, and finally the results of some simple cross-sectional regressions suggested by the model.

A. Taking the model to the data

A.1. The cross-section of asset classes

A key testable implication of our model is that, all else equal, traditional banks should hold a higher market share in more illiquid assets: $\frac{\partial (1 - \mu^*_i)}{\partial \phi_i} > 0$.

**Prediction 1:** Looking across assets and holding constant fundamental asset risk, banks should have a larger market share in asset classes that are more illiquid.

Our model features just two intermediary types: traditional banks with stable funding and shadow banks with unstable funding. In reality, there are many intermediary types with a range of funding stability. Generalizing our theory, we would expect intermediaries with more stable funding to hold more illiquid assets with high fire-sale risk.

**Prediction 2:** Looking across assets and holding constant fundamental asset risk, more illiquid asset classes should be held by intermediary types with greater funding stability.

A.2. The cross-section of intermediary types

Since our theory has predictions for the cross-section of asset types, it naturally generates related predictions for the cross-section of intermediary types. Specifically, the portfolio share of shadow banks in asset $i$ is

$$w^s_i = \frac{\mu^*_i Q_i}{\sum_{k=1}^N \mu^*_k Q_k},$$

and the portfolio share of traditional banks in asset $i$ is
\[ w_i^{bs} = \frac{(1 - \mu_i^*)Q_i}{\sum_{k=1}^{N}(1 - \mu_k^*)Q_k^*}. \] (11)

It follows trivially from the comparative statics derived above that \( \partial w_i^{sx} / \partial \varphi_i < 0 \), \( \partial w_i^{sx} / \partial z_i < 0 \), \( \partial w_i^{bs} / \partial \varphi_i > 0 \), and \( \partial w_i^{bs} / \partial z_i > 0 \). In other words, shadow bank portfolios are tilted towards assets that are more liquid or have more fundamental downside-risk, whereas traditional bank portfolios are tilted towards assets that are more illiquid and have less fundamental downside-risk.

The average illiquidity of assets held by shadow banks is

\[ \Phi^{sx} = \sum_{i=1}^{N} w_i^{sx} \varphi_i, \] (12)

and the average illiquidity of asset held by commercial banks is

\[ \Phi^{bx} = \sum_{i=1}^{N} w_i^{bx} \varphi_i. \] (13)

If all assets have the same \( z_i \), in equilibrium we have

\[ \Phi^{bx} > \Phi^{sx}. \] (14)

That is, the asset portfolios of traditional banks would be more illiquid than those of shadow banks.

**Prediction 3:** The asset portfolios of commercial banks are more illiquid than the asset portfolios of shadow banks, controlling for fundamental risk.

As above, we can generalize this to obtain a prediction that we can apply to the broader cross-section of intermediary types, including insurers and finance companies.

**Prediction 4:** Comparing across intermediaries, those with more stable funding should have asset portfolios that are more illiquid, controlling for fundamental risk.

B. **Measurement**

Let \( j \) index intermediary types and let \( i \) index instrument types—i.e., different types of assets or liabilities. Let \( ILLIQUID_i \in [0,1] \) measure the illiquidity of asset type \( i \). For instance, US Treasuries should have \( ILLIQUID_i = 0 \) and small business loans might have \( ILLIQUID_i = 1 \). Similarly, let \( MATURITY_i \in [0,1] \) measure the contractual maturity length of liability type \( i \) and \( STICKY_i \in [0,1] \) measure the stickiness of liability type \( i \). Stickiness is opposite of runniness, which is the tendency for liability holders to withdraw funds following an adverse shock. For instance, short-term commercial paper might have \( STICKY_i = 0 \), while long-term (non-redeemable) equity would have \( STICKY_i = 1 \).
Let $A_{ji}$ and $L_{ji}$ denote intermediary $j$’s assets and liabilities of instrument type $i$ and let $A_j = \sum_i A_{ji}$, $L_j = \sum_i L_{ji}$ denote the total assets of intermediary type $j$. Then the Asset Illiquidity Index for intermediary type $j$ is defined as the weighted average illiquidity of its asset holdings

$$A_{ILLIQUID,j} = \frac{\sum_i A_{ji} \times ILLIQUID_i}{A_j}. \quad (15)$$

The Liability Maturity Index for intermediary type $j$ is the weighted average contractual maturity of its liabilities

$$L_{MATURITY,j} = \frac{\sum_i L_{ji} \times MATURITY_i}{A_j}. \quad (16)$$

Finally, the Liability Stickiness Index for intermediary type $j$ is the weighted average stickiness of its liabilities

$$L_{STICKY,j} = \frac{\sum_i L_{ji} \times STICKY_i}{A_j}. \quad (17)$$

Our measurement approach is in the spirit of Brunnermeier, Gorton, and Krishnamurthy (2011, 2013), who suggest constructing a liquidity mismatch index—the difference between asset illiquidity and funding liquidity—for different financial intermediaries. This approach is implemented in Bai, Krishnamurthy, and Weymuller (2013) for bank holding companies.

We assemble data on the assets and liabilities of various types of financial intermediaries using the Federal Reserve’s Financial Accounts of the United States (formerly the Flow of Funds Accounts). We examine data on commercial banks, property and casualty (P&C) insurers, life insurers, money market funds (MMFs), government sponsored enterprises (GSEs), finance companies, real estate investment trusts (REITs), and security broker-dealers. We use data on intermediary balance sheets as of 2012Q4. However, the findings of our analysis do not depend significantly on when we look at the data.

In an effort to avoid subjective judgments, wherever possible we assign numerical values for $ILLIQUID_j$, $MATURITY_j$, and $STICKY_j$ based on the bank liquidity requirements recently put forth under Basel III Accord. (To be clear, these new liquidity requirements are distinct from the more familiar risk-based capital requirements.) Specifically, for each instrument type, we attempt to choose values of these parameters based on the proposed calibration of Basel III’s Net Stable Funding Requirement (NSFR) in Basel Committee on Banking Supervision (2010) and the final calibration of the Liquidity Coverage Ratio (LCR) in Basel Committee on Banking Supervision.
Hereafter BCBS (2010 and 2013). However, we do need to apply some judgment in mapping the instrument types considered by Basel III to our aggregated Financial Accounts data. We also need to assign values for liability types issued by non-banks that are not considered by BCBS. As we detail in Appendix B, we have made every attempt to do so in the spirit of BCBS (2010 and 2013) and consistent with empirical evidence. The most important auxiliary assumption we make is that the policy-related liabilities of life insurers are quite sticky whereas those of P&C insurers are somewhat less sticky.21

Consider first our ILLIQUID index for assets. We associate ILLIQUID with the parameter $\phi_i$ in the model. We assign $ILLIQUID = 0$ for US Treasuries, $ILLIQUID = 0.15$ for GSE-backed MBS, $ILLIQUID = 0.5$ for corporate equities, $ILLIQUID = 0.75$ for consumer debt and home mortgages, and $ILLIQUID = 1$ for unsecured (C&I) and secured commercial real estate (CRE) loans.

Next, consider our STICKY and MATURITY indices for liabilities. Starting with bank deposits, we assign $STICKY = 0.7$ and $MATUREY = 0.1$ for wholesale bank deposits, $STICKY = 0.8$ and $MATUREY = 0$ for retail time and savings deposits, and $STICKY = 0.9$ and $MATUREY = 0$ for transactions deposits. Turning to non-deposit liabilities, we assign $STICKY = 0.6$ and $MATUREY = 0.6$ for corporate bonds and $STICKY = 0$ and $MATUREY = 0$ for non-deposit, short-term funding. For insurance policy liabilities, we assume $STICKY = MATURITY = 0.9$ for life policies and $STICKY = MATURITY = 0.6$ for P&C policies.

C. Empirical tests

C.1 The cross-section of asset classes

Prediction 1 says that traditional banks should hold a higher market share in more illiquid assets. A simple way to assess this prediction is to compute banks’ market share for each asset type

$$BANK\_SHR_i = A_{bank,i} / \sum_j A_{ji}. \quad (18)$$

In other words, for each asset type, we compute banks’ share of the total amount of assets held by financial intermediaries.22 Since $BANK\_SHR_i$ corresponds precisely to $(1-\mu_i)$ in the model and $ILLIQUID_i$ corresponds to $\phi_i$, we should see a strong positive relationship between $BANK\_SHR_i$ on $ILLIQUID_i$ in the cross-section of asset types.

---

21 See Bai, Krishnamurthy, and Weymuller (2013) for a similar, albeit more sophisticated, approach that requires more granular balance sheet data than is available in the Financial Accounts. Specifically, they use measures of asset illiquidity based on repo haircuts.

22 Specifically, we compute the share of assets held by the Financial Business sector in table L.107 that is attributable to U.S.-Chartered Depository Institutions in table L.110.
Panel A of Figure 3 shows the result. The estimated regression is

\[ BANK\_SHR_i = 0.04 + 0.57 \times ILLIQUID_i, \quad R^2 = 0.47. \]  

(19)

As predicted, there is a strong positive relationship between asset illiquidity and banks’ market share. Of course, this is just a descriptive cross-sectional regression with 12 observations. It is also a univariate regression, whereas our theory suggests a bivariate relationship: banks’ market share of a given asset should depend on both the asset’s illiquidity and its fundamental safety. If the two characteristics are correlated—as they likely are—then (19) suffers from an omitted variable bias. To address this concern, we run a multivariate regression of banks’ market share on asset illiquidity and fundamental safety, expecting positive coefficients on both. To run this multivariate regression, we create a new variable called \( \text{FUNDSAFE} \), which we set equal to negative one times the risk-weight under current U.S. risk-based capital regulations.\(^{23}\) While this is solely meant to be illustrative, this approach yields

\[ BANK\_SHR_i = 0.14 + 0.68 \times ILLIQUID_i + 0.16 \times \text{FUNDSAFE}_i, \quad R^2 = 0.73. \]  

(20)

The coefficient on \( ILLIQUID_i \) is larger in the multivariate regression and the \( R^2 \) rises considerably. Alternatively, we can go back to running a univariate regression of banks’ market share on illiquidity alone, simply dropping those asset classes with significantly greater fundamental cashflow risk. For instance, if we drop equity-like instruments (corporate equities and mutual fund shares), the \( R^2 \) in the univariate regression rises from 0.47 to 0.59.

Turning to Prediction 2, other intermediaries besides traditional banks may also have stable funding and thus may also have a comparative advantage at holding illiquid assets. To capture this we compute the average funding stability of holders of a given asset as

\[ AV\_STICKY_i = \frac{\sum_j A_{ji} \times L\_STICKY_j}{\sum_j A_{ji}}. \]  

(21)

Since \( AV\_STICKY_i \) is a generalized version of \((1-\mu_i)\) in the model and \( ILLIQUID_i \) corresponds to \( \varphi_i \), Prediction 2 suggests that we should observe a strong positive relationship between the two in the cross-section. This is shown in Panel B of Figure 3 where we plot \( AV\_STICKY_i \) versus \( ILLIQUID_i \). The estimated regression is given by

\[ AV\_STICKY_i = 0.59 + 0.23 \times ILLIQUID_i, \quad R^2 = 0.41. \]  

(22)

Again, we see a strong positive relationship. The \( R^2 \) of this regression rises from 0.41 to 0.64 if we exclude corporate equities and mutual fund shares.

Figure 3 confirms the core message of our model. Banks hold virtually no Treasuries despite their extreme safety. Treasuries are not exposed to interim fire-sale risk, so they are not profitable enough for banks. By contrast, banks are significant holders of GSE-backed MBS. These securities have limited downside risk, so banks can use them to back nearly as much safe short-term debt as a shadow bank. At the same time, GSE-backed MBS are more exposed to fire-sale risk than Treasuries, which makes them more attractive to traditional banks.

Figure 3 also shows that banks have a dominant market share in illiquid home mortgage loans, holding approximately 76% of unsecuritized whole loans. Banks are also the largest holders of illiquid commercial and multi-family home mortgages. Going beyond Figure 3, even within the category of home mortgages, banks tend to hold less “plain-vanilla” products, for which liquidation costs are likely higher. Specifically, banks are the dominant holders of second-lien home equity loans and other mortgage products falling outside of the conventional mortgage markets supported by the GSEs.\(^{24}\)

Finally, Figure 3 shows that banks remain significant holders of unsecured loans to firms, holding 48% of all C&I loans. As with home mortgages, when one looks within the category of C&I loans, banks seem to specialize in those that are the most illiquid. For instance, banks have been steadily losing market share in the market for C&I loans to large firms, which has become increasingly liquid in recent decades. At the same time, banks remain the near exclusive providers of C&I loans to small- and medium-sized firms, which continue to be highly illiquid. According to the 2012Q4 Financial Accounts, banks hold 37% of C&I loans to non-financial corporations, but 86% of C&I loans to non-financial non-corporate businesses, which tend to be much smaller.

### C.2 The cross-section of intermediary types

Prediction 4 suggests that in the cross-section of intermediary types we should see a strong positive relationship between \( A_{ILLIQUIDj} \) and \( L_{STICKYj} \). Since the stickiness of liabilities as opposed to their contractual maturity is the key to avoiding costly liquidations, we expect to see weaker relationship between \( A_{ILLIQUIDj} \) and \( L_{MATURITYj} \). In particular, we expect traditional

---

\(^{24}\) For instance, according to the Financial Accounts, commercial banks held 85% of the $750 billion in second-lien home mortgages loans as of 2012Q4.
banks to look like an extreme outlier in this regard because their assets are highly illiquid given the short contractual maturity of their liabilities.

Panel A of Figure 4 plots $A_{ILLIQUID}$ versus $L_{STICKY}$. As predicted by the theory, we see a strong positive relationship and the estimated regression is

$$A_{ILLIQUID} = 0.13 + 0.55 \times L_{STICKY}, \quad R^2 = 0.64. \quad (23)$$

Panel B of Figure 4 plots $A_{ILLIQUID}$ versus $L_{MATURITY}$. The estimated regression is

$$A_{ILLIQUID} = 0.27 + 0.36 \times L_{MATURITY}, \quad R^2 = 0.29. \quad (24)$$

So, as expected, the regression fit deteriorates significantly from Panel A to Panel B. Although there is a general tendency for intermediaries with longer maturity liabilities hold more illiquid assets, banks are a significant outlier. Relative to other patient investors, who obtain stable funding by issuing liabilities with long contractual maturities, banks issue short-term liabilities but organize themselves in such a way that their contractually short-term deposits are de facto extremely stable.

D. Related micro evidence

While we have focused on the aggregate structure of financial intermediation, the banking literature contains some complementary micro evidence also consistent with our theory. Using the Survey of Terms of Business Lending, Berlin and Mester (1999) find that, in the cross-section of banks, those with greater access to sticky “core” deposits (i.e., transaction and saving deposits) are more likely to form stable lending relationships with firms, thereby providing borrowers with insurance against transitory market shocks. Black, Hancock, and Passmore (2007 and 2010) find that banks with a large supply of core deposits tend to specialize in more illiquid information-intensive loans, whereas banks which are more reliant on wholesale funding tend to specialize in easy-to-value loans.\(^ {25} \)

VI. Normative Implications

A central set of issues in current discussions of financial regulation concerns the migration of intermediation activity from the traditional banking sector to the shadow banking sector. Our model has some interesting normative implications about whether and where policy-makers should

---

\(^ {25} \) Black, Hancock, and Passmore (2007) show that there is strong positive association between core deposit taking and small business lending, while Black, Hancock, and Passmore (2010) find an similar connection between core deposits and information-intensive (i.e., subprime) mortgage lending.
attempt to counteract such migration. Specifically, shadow banking creates negative externalities in our model, as the social costs of fire sales exceed the private costs. This is because the ability of shadow banks to create money-like claims is constrained by the time-1 liquidation value of their collateral. An intermediary that switches from traditional to shadow banking fails to internalize how this switch reduces liquidation prices and, thus, the feasible amount of money creation by other shadow banks.

If it is also possible to create some private money via traditional banking (i.e., if $z_i>0$), the private-market equilibrium features a shadow banking sector that is too large and a traditional banking sector that is too small, as compared to the social optimum. A regulator wishing to restore the social optimum may be able to do so by imposing a set of minimum required haircuts on shadow banks, in an effort push money creation back to traditional banks. These regulatory haircuts are effectively an extra capital requirement that the shadow banking sector must set aside when raising short-term funding against risky assets, above and beyond what the private sector demands simply to make the short-term claims safe. Specifically, a regulator imposing an additional haircut of $h_i$ only allows shadow banks to create $(k_i - h_i)F_i < k_i F_i$ of safe claims using the risky asset $i$ as collateral. These haircuts function as a Pigouvian tax on the fire-sale externality associated with the shadow-banking sector.

In the Appendix, we show that, in the simple case where there are no social costs associated with the provision of government deposit insurance, these optimal shadow-banking haircuts, given by $h_i^{**}$, have a simple and intuitive form:

$$h_i^{**} = \eta(\varphi_i) \frac{z_i}{1-\eta(\varphi_i)} F_i > 0.$$  \hspace{1cm} (25)$$

Here $\eta(\varphi_i)$ denotes the elasticity of the fire-sale discount with respect to liquidation volume and is an increasing function of asset illiquidity $\varphi_i$. Thus optimal haircut requirements depend on two factors. First, the required haircut is larger for more illiquid assets. This is natural since $\eta(\varphi_i)$ captures the severity of the fire-sale externality—i.e., the strength of the over-migration tendency. Second, the optimal haircut is higher for assets with high values of $z_i$—i.e., for assets with little fundamental risk. These are the assets where traditional banks’ stable, hold-to-maturity strategy can create the most monetary services. If traditional banking does not create any un-internalized social
costs, one wants to lean most aggressively against shadow banking in those cases where traditional banks provide an efficient alternative.\textsuperscript{26}

To generate a more complete and balanced policy analysis, one can take account of the fact that traditional banking also gives rise to social costs that are not fully internalized. Since bank capital is completely wiped out in the disaster state of the world, creating safe bank deposits inevitably exposes taxpayers to some tail risk. This could be socially costly to the extent that deposit insurance creates moral hazard problems, government fiscal capacity is limited (Stavrakeva 2013), or traditional banks do not fully understand tail risks (see Gennaioli, Shleifer, and Vishny 2012 and 2013). For simplicity, in the Appendix we assume that these insurance payouts are financed by distortionary taxes which create deadweight social losses.

With this modification, the Appendix shows that the optimal haircut in \textsuperscript{(25)} is reduced by a term that reflects the marginal fiscal cost of relying on taxpayer-financed deposit insurance. This cost is greater when the disaster state is more likely, when the scale of the resulting bailout is larger (i.e., when the traditional banking system is larger), and when a given amount of taxation creates greater deadweight losses.

\section*{VII. Conclusion}

We have argued that the specialness of traditional banks comes from combining stable money creation on the liability side with assets that have relatively safe long-run cash flows but possibly volatile market values and limited liquidity. To make this business model work, banks rely on deposit insurance, and bear the associated costs of capital regulation.

Some preliminary evidence is consistent with the model’s predictions. Historically, prior to the introduction of deposit insurance, U.S. commercial banks relied on deposits as their primary source of funding—just as they do today—but invested in assets that were much shorter term and less volatile than they do now. The change in the structure of bank assets, and not just in the stability of their deposits, as a result of deposit insurance, is a distinctive prediction of our model.

In the cross-section of fixed income assets, the most illiquid assets have the highest share held by commercial banks. As the model predicts, banks specialize in holding relatively safe fixed

\textsuperscript{26} For example, our model implies that $h_1^* = 0$ for equity-like assets where $z_i = 0$—in other words, there is no need for regulation in this case. This is because when $z_i = 0$, shadow banking is the only technology for creating money-like claims, so there is no scope for over-migration. However, when $z_i > 0$, there is also a stable banking technology (which is socially costless by assumption) to migrate away from.
income assets but are not afraid of illiquidity. In a cross-section of types of financial intermediaries, intermediaries with stickier liabilities hold less liquid assets. Banks, in particular, appear as having extremely sticky liabilities, as well as very illiquid assets. More casual evidence, such as the near absence of both Treasuries and equities in bank asset portfolios, also supports our view.

One key message of the paper is that the structure of financial intermediation may be shaped in important ways by the non-fundamental movements in asset prices—due to fire sales, noise trading, slow-moving capital, and other frictions—that have been extensively documented in the asset-pricing literature. Specifically, one central role of intermediaries—and of banks in particular—is to act as a bridge between households who want to put their money in a safe place they do not need to watch, and securities markets where even assets with relatively low fundamental risk can have volatile market prices.

Appendix

A. Estimating the Profitability of Narrow Banking

We estimate the profitability of narrowing bank using

$$\Pi = (R_F - R_{DEP}) + \frac{NONINTINC}{DEP} - \frac{NONINTEXP}{DEP}. \tag{A1}$$

The text describes the computation of all the components of (A1) for the US commercial banking industry, except for the non-interest expense associated with deposit-taking \(\text{NONINTEXP/DEP}\). This term is not directly available from Call Reports: banks report their total noninterest expense, but we are only interested in those expenses attributable to deposit-taking.

To get an estimate of the expenses associated with deposit taking, we adopt a simple hedonic approach. Specifically, each year we run a cross-sectional regression of \(\text{NONINTEXP}_{it}/\text{ASSET}_{it}\) on asset shares, liability shares, and other controls:

$$\frac{\text{NONINTEXP}_{it}}{\text{ASSET}_{it}} = \alpha_t + \sum_{k=1}^{K} \beta_t^{(k)} \frac{\text{ASSET}_{it}^{(k)}}{\text{ASSET}_{it}} + \sum_{j=1}^{J} \gamma_t^{(j)} \frac{\text{DEPOSIT}_{it}^{(j)}}{\text{ASSET}_{it}} + \theta^t \mathbf{x}_i + \epsilon_{it}. \tag{A2}$$

We choose the independent variables so that the intercept term for year \(t\), \(\alpha_t\), can be interpreted as the operating expenses associated with a “mutual-fund-like” bank that owns a portfolio of long-term marketable securities and finances these assets using only wholesale funding and equity. The slope coefficients in (A2) are interpretable as unit noninterest expenses associated with various activities.

We use cross-sectional variation in banks’ asset mix to identify the \(\beta_t^{(k)}\). We control for real estate loans \((\text{RELOAN}_{it}/\text{ASSET}_{it})\), C&I loans \((\text{CILOAN}_{it}/\text{ASSET}_{it})\), consumer loans \((\text{CONLOAN}_{it}/\text{ASSET}_{it})\), other loans \((\text{OTHLOAN}_{it}/\text{ASSET}_{it})\), and trading assets \((\text{TRADING}_{it}/\text{ASSET}_{it})\). Liquid assets (cash, interbank loans, and securities) and other assets are the omitted categories absorbed in \(\alpha_t\). To identify the \(\gamma_t^{(j)}\), we control for transaction deposits \((\text{TRANSDEPOSIT}_{it}/\text{ASSET}_{it})\), savings deposits \((\text{SAVEDEPOSIT}_{it}/\text{ASSET}_{it})\), and foreign deposits \((\text{FORDEPOSIT}_{it}/\text{ASSET}_{it})\). Time deposits and other borrowed money are the omitted liability categories that are absorbed in \(\alpha_t\). Finally, we control for bank size \((\ln(\text{ASSET}_{it}))\) and noninterest income not associated with deposit-taking or credit intermediation \((\text{OTHNONINTIC}_{it}/\text{ASSET}_{it})\).\(^{27}\)

\(^{27}\) This exercise can be seen as a simple way of estimating bank cost functions. There is a vast technical literature on this subject. See, for instance, Hughes and Mester (2010) for a recent review.
The coefficients for transaction deposits and saving deposits are of primary interest for our cost attribution analysis and are shown in Figure A1. These coefficients are interpretable as the unit noninterest expenses associated with various types of deposit-taking. For instance, the coefficient of 3.4% for transaction deposits in 1984 means that a bank which was 100% funded with transaction deposits had an expense ratio 3.4 percentage points higher than the baseline wholesale-funded bank.\(^{28}\)

Figure A1 shows that estimated unit cost of transaction deposits has fallen steadily over time, from 3.4% to 1984 to only 0.5% in 2012. This downward trend makes sense in light of the numerous technological developments, primarily information technology, that have reduced the costs of deposit-taking. In contrast, Figure A1 shows that the unit cost of savings deposits hovered around 2% from the late 1980s to 2008. However, the costs of savings deposits has fallen sharply in the past 4 years, arguably because banks have benefited from large deposit inflows due to the low-interest rate environment and expanded FDIC guarantee programs.

Using these cross-sectional regression coefficients as our proxies for the relevant unit costs, we estimate the aggregate noninterest expense associated with deposit-taking activities as

\[
\frac{\text{NONINEXP}^{\text{DEP}}_t}{\text{DEPOSIT}_t} = \frac{\text{ASSET}_t}{\text{DEPOSIT}_t} \times \left( \frac{\gamma^{(\text{TRANS})}_t \cdot \text{TRANSDEPOSIT}_t}{\text{ASSET}_t} + \frac{\gamma^{(\text{SAVE})}_t \cdot \text{SAVEDEPPOSIT}_t}{\text{ASSET}_t} + \frac{\gamma^{(\text{FOR})}_t \cdot \text{FORDEPOSIT}_t}{\text{ASSET}_t} \right). \tag{A3}
\]

In other words, to come up with an estimate of deposit-related operating costs, we apply our estimated unit costs to the deposit mix of the aggregate banking industry.

Figure A2 shows the time series of estimated profits from deposit taking from 1984–2012. We first show the gross deposit spread, \(R_F - R_{\text{DEP}}\), which is the net interest income associated with narrow banking. The interest rates paid on transactional and savings deposit accounts embed a significant convenience premium relative to short-term market rates. As a result, the gross deposit

\(^{28}\) The dashed lines are standard error bands and indicate that the parameters are precisely estimated which is natural since there are thousands of banks in each cross-section.

44
spread averages 0.87% of deposits over our 29 year sample.\textsuperscript{29} We next add noninterest income associated with deposit taking, $\text{NONINTINC}/\text{DEP}$, which has averaged 0.49% of deposits.

Finally, we subtract our estimate of the noninterest expense associated with deposit-taking. While estimated deposit-taking expenses have trended down steadily over time, these expenses are substantial, averaging 1.30% of deposits. Combining these pieces as in equation (A1), we arrive at our estimates of the profits generated by narrow banking. Between 1984 and 2012, these profits average 0.06% of deposits.

This 0.06% figure is an upper bound on the profitability of narrow banking. Specifically, as noted above, our attribution of non-interest expenses includes an unallocated fixed overhead cost which is not attributed to deposit-taking or lending at the margin. These overhead costs are significant, and average 0.63% of deposits from 1984-2012. Thus, one needs to ask how much of these fixed overhead costs should be allocated to deposit-taking. If 50% of these fixed costs are allocated to deposit-taking, the estimated profitability of narrow banking falls to -0.25% on average.

B. Cross-section of Intermediary Types and Cross-section of Assets

We assemble data on the financial assets and liabilities of various intermediary types from the Federal Reserve’s Financial Accounts of the United States (formerly the Flow of Funds Accounts). We examine data on commercial banks, property and casualty (P&C) insurers, life insurers, money market funds (MMFs), government sponsored enterprises (GSEs), finance companies, real estate investment trusts (REITs), and security broker-dealers.

We exclude a handful of financial sectors included in the Financial Accounts. First, we exclude the Federal Reserve (L.108), taking the view that it should be consolidated with the Federal Government from the standpoint of financial intermediation. Second, we exclude pension funds (L.116), mutual funds (L.121), and closed-end funds and ETFs (L.122) on the theory that these “real money” intermediaries are essentially just veils for the household sector. Third, to avoid double-counting issues we do not treat MBS and ABS issuers as separate sectors. Finally, we exclude Holding Companies (L.129) and Funding Corporations (L.130).

\textsuperscript{29} As shown in Figure A2, the net interest income generated by deposit-taking is positively related to the level of short-term interest rates. This is because the rates on transaction and savings deposits adjust very sluggishly to movement in short-term market rates. See Neumark and Sharpe (1992) and English, Van den Heuvel, and Zakrajsek (2012).
For each financial intermediary type, we construct an aggregate balance sheet using data in the Financial Accounts. This requires some straightforward manipulation of the Financial Accounts Data. There are three minor subtleties. First, we do not count GSE-backed MBS—which were consolidated onto their balance sheets following the implementation of FASB 140 in December 2010—as GSE assets. Second, to operationalize equation (18) for banks’ market share in each asset class, we compute banks’ holdings as a share of all assets held by the domestic Financial Business sector in Table L.107. In other words, we compute banks’ share of intermediated assets holdings. Third, for each category of loans (home mortgages, commercial mortgages, multifamily mortgages, consumer loans, and C& loans) we adjust the amount of outstanding loans to net out securitized loans. Thus, holdings of these assets represent intermediaries’ holdings of (whole) loans, whereas holdings of securitizations are accounted for separately as either holdings of GSE-backed MBS or as corporate bonds for private securitizations.

Next we need to choose values for $I_{LIQUID_j}$, $MATURITY_j$, and $STICKY_j$. Our approach is to choose values based on the liquidity risk measurement proposal set forth under Basel III. We use parameter values associated with the BCBS (2010) proposal for the Net Stable Funding Requirement (NSFR) and the final BCBS (2013) Liquidity Coverage Requirement (LCR). First, using BCBS (2010), we use the NSFR’s Required Stable Funding factor as a first guide for assigning $I_{LIQUID_j}$ and the Available Stable Funding factor as guide for $STICKY_j$. Second, using BCBS (2013), we used the LCR’s haircut factor for the computation of High Quality Liquid Assets as a second guide for $I_{LIQUID_j}$ and the assumed percentage outflow factor as second guide for $STICKY_j$. The inputs from the NSFR and LCR are summarized in Table AI.

Our approach is to use these BCBS factors whenever possible. In general, the NFSR and LCR factors paint a similar picture of asset illiquidity and liability maturity and stickiness. However, when the two are in conflict we lean towards the LCR weights, reasoning that they represent the most up-to-date consensus among policy-makers and market participants.

There are some categories such as GSE-debentures and corporate bonds where it does not make sense to assume $STICKY = 1$ and $MATURITY = 1$: some of these bond are short-term and are prone to run. Therefore, we assume $STICKY = MATURITY = 0.4$ in both cases.

We also need to assign values for liability types issued by non-banks that are not considered by BCBS (2010, 2013). We are forced to fill in these assumptions. However, we have made every
attempt to do so in a way that is consistent with the spirit of Basel III and is motivated by existing empirical evidence wherever possible. The main question here concerns the length and stickiness of the policy-related operating liabilities of life and P&C insurers. We assume that both life and P&C policies are fairly illiquid assets with $ILLIQUID = 0.4$. In the case of life policy liabilities, we assume $STICKY = MATURETY = 0.9$ so the liabilities of life insurers are comparable to retail bank deposits. For P&C insurers, we assume that $STICKY = MATURETY = 0.6$, so the liabilities of P&C insurers are equivalent to corporate bonds. Our final parameter choices are shown in Table AII.

C. Policy Analysis

C.1. Determination of the Fire-Sale Discount

Before getting into the policy analysis, we need to be a bit more explicit about the origins of the fire-sale discount in our model. Recall the key reduced-form properties we have assumed about this discount, namely that $\partial k(\mu_i, \varphi_i) / \partial \mu_i \leq 0$, so demand is downward sloping, and that $\partial^2 k(\mu_i, \varphi_i) / \partial \mu_i \partial \varphi_i \geq 0$, so more illiquid assets have steeper demand curves.

These properties can be micro-founded in an elaborated version of Stein (2012). For each asset $i$, we assume that there is a separate group of $n_i$ specialist buyers, who can step in and buy the asset if it is liquidated at time 1. As will become clear momentarily, assets with low values of $n_i$ correspond to those with high values of $\varphi_i$. In other words, asset illiquidity ultimately derives from the fact that there are relatively few specialist buyers available to absorb a given asset.

Specialist buyers are also owned by households: all their profits accrue to households at time 2. Each individual specialist buyer has war chest of $0 < W \leq 1$ available at time 1, which can be used either to buy up fire-sold assets at a discount, or to invest in new real projects. Each specialist buyer’s investment of $K_i$ in a new project yields a gross return of $g(K_i) = \log(K_i)$. Recall that liquidated assets sell at a discount $k_i$ to their fundamental value of $F_i = qR + (1-q-\varepsilon)z_i$ and thus yield a gross expected return of $1/k_i$ to a specialist buyer who purchases them at time 1. Since the total volume of liquidations in asset $i$ is $\mu_i k_i F_i$, and since these liquidations must be absorbed by $n_i$ specialist buyers, each buyer must absorb $\mu_i k_i F_i / n_i$ of the liquidation, investing $K_i = W - \mu_i k_i F_i / n_i$ in new projects. At an interior optimum, the expected return to buying fire-sold assets must be equal to the expected return to investment in the new project, which implies:
Given our functional form assumption that $g(K_i) = \log(K_i)$, this expression boils down to:

$$k_i = \frac{W}{1 + \mu_i F_i / n_i}.$$  \hfill (C2)

Since $n_i$ is nothing more than an inverse measure of asset illiquidity $\phi_i$, we now have a micro-founded expression for the fire-sale discount $k_i$ with the desired properties that $\partial k(\mu, \phi_i) / \partial \mu_i \leq 0$ and $\partial^2 k(\mu, \phi_i) / \partial \mu_i \partial \phi_i \leq 0$. (The former always holds and the latter holds so long as $n_i \geq \mu_i F_i$ which we henceforth assume). Furthermore, we have

$$\eta_i = \frac{-k_i'(\mu_i)\mu_i}{k_i(\mu_i)\mu_i F_i + n_i},$$  \hfill (C3)

so, all else equal, the elasticity of the fire-sale price with respect to $\mu_i$ is greatest for illiquid assets with few specialist buyers $n_i$.

While this micro-founding exercise is extremely simple, it is necessary for the normative analysis that follows. This is because in order to model the social costs of fire sales, we need to relate the costs to the foregone real investment by the specialist buyers that is an inevitable consequence of these fire sales. With this bit of machinery in place, we can now examine the policy implications of the model.

### C.2. Optimal Haircuts

We assume that any deposit insurance payout in the disaster state is financed with distortionary taxes and, therefore, imposes an additional cost on households. Specifically, we assume that an insurance payout of $X$ gives rise to distortionary fiscal costs of $(\lambda/2)X^2$. The payout associated with asset $i$ in the disaster state is $X = (1-\mu_i)z_i$ which is borne with probability $(1-p)\epsilon$, implying that traditional banking gives rise to an expected fiscal cost of $(1-p)\epsilon(\lambda/2)((1-\mu_i)z_i)^2$.

Since households own shadow banks, traditional banks, and specialist buyers, the household utility associated with asset $i$ equals the value of all shadow and traditional banking claims backed by $i$, plus the expected profits earned by associated specialist buyers, less the expected fiscal cost:

$$U_i = \mu_i V_i^S(\mu_i) + (1-\mu_i)V_i^B + \beta n_i(E[g(K_i) - K_i] + (1-p)(\mu_i F_i / n_i)(1/k_i - 1) - (1-p)\epsilon(\lambda/2)((1-\mu_i)z_i)^2).$$  \hfill (C4)
As shown in (C3), the expected profits earned by each specialist buyer are the sum of their expected net return on new real investment, \( E[g(K_i) - K_i] \), plus their expected net return on asset purchases in the pessimistic-news state, \((1 - p)(\mu k_i F_i / n_i) (1 / k_i - 1)\).

However, since the fire-sale losses incurred by shadow banks represent a gain for specialist buyers, the terms of trade between these intermediaries cancel out from the standpoint of household welfare. As a result, the relative size of the traditional banking and shadow banking sectors only impacts household welfare in three ways: the initial amount of monetary services enjoyed by households, the magnitude of the fire-sale problem as captured by the amount of specialist buyer output following pessimistic news at time 1, and the expected fiscal costs. One can think of specialist output as a stand-in for the severity of the collapse in real output if pessimistic news arrives at time 1, triggering a financial crisis. Specifically, ignoring irrelevant constants, initial household utility is given by:

\[
U_i = \gamma M_i + \beta (1 - p) n_i [g(K_i) - K_i] - (1 - p) \varepsilon (\lambda / 2) [(1 - \mu_i) z_i]^2.
\]

\[
= \gamma [\mu_i k_i F_i + (1 - \mu_i) z_i] + \beta (1 - p) n_i [g(W - \mu_i k_i F_i / n_i) - (W - \mu_i k_i F_i / n_i)]
- (1 - p) \varepsilon (\lambda / 2) [(1 - \mu_i) z_i]^2.
\] (C5)

The second line of equation (C4) follows from the fact that the total amount of money created by shadow banks and traditional banks using asset \(i\) as backing is \(M_i = \mu_i k_i F_i + (1 - \mu_i) z_i\), plus the fact that each specialists’ investment in new real projects following pessimistic news is \(K_i = W - \mu_i k_i F_i / n_i\).

Since intermediaries pick \(\mu_i\) taking \(k_i\) as given and ignoring the external fiscal costs, the private market equilibrium studied in the text corresponds to

\[
\max_{\mu_i \in [0,1]} \{\gamma [\mu_i k_i^* F_i + (1 - \mu_i) z_i] + \beta (1 - p) n_i [g(W - \mu_i k_i^* F_i / n_i) - (W - \mu_i k_i^* F_i / n_i)]\},
\] (C6)

where we use one star to denote the private market solution. Recalling that \(1 = k_i g(W - \mu_i k_i F_i / n_i)\), the first order condition for (C6) implies that an interior private market equilibrium satisfies

\[
[yk_i^* - (1 - p) \beta (1 - k_i^*)]F_i = [\gamma z_i],
\] (C7)

which is equivalent to equation (6) in the main text.

By contrast, a social planner chooses \(\mu_i\) to maximize household utility (C5). Relative to the private market equilibrium described in the text, the social planner’s solution also takes into account
the fact that \( k_i'(\mu_i) < 0 \) as well as the fiscal costs associated with deposit insurance. The first order condition for this problem implies that an interior social optimum must satisfy

\[
\eta_i = \frac{\text{Elasticity of fire-sale price}}{\text{Shadow banking}} \times \frac{\text{Net private benefit}}{\text{Shadow banking}} (1 - \frac{[-k_i'(\mu_i^*)\mu_i^* - k_i(\mu_i^*)]}{k_i(\mu_i^*)}) \times [\gamma k_i(\mu_i^*) - \beta(1 - p)(1 - k_i(\mu_i^*))] F_i
\]

where we use two stars to denote the social planner’s solution. Relative to (C7), the net private benefit of shadow banking is reduced by a factor that depends on the elasticity of the first-sale price with respect to \( \mu_i, \eta_i = -k_i'(\mu_i)\mu_i / k_i \). Furthermore, the net private benefit of traditional banking is reduced by the marginal fiscal cost of the associated deposit insurance payouts.

A planner can implement the social optimum as a decentralized equilibrium by imposing an additional haircut requirement on the amount of repo that shadow banks can issue to MMFs. Although the private market imposes a haircut, the planner needs to require even larger haircuts so shadow banks can only create \( (k_i^* - h_i^*)(F_i < k_i^*F_i) \) of safe repo using asset \( i \) as collateral. A shadow bank subject to a regulatory haircut requirement of \( h_i \) has value

\[
V_i^S(k_i, h_i) = \gamma (k_i - h_i) F_i + \beta [pR + (1 - p)k_i F_i].
\]

Equation (25) in the text is just the special case of (C10) when there are no fiscal costs associated with deposit insurance, i.e., when \( \lambda = 0 \).
