Rationalizable Partition-Confirmed Equilibrium with Heterogeneous Beliefs

Drew Fudenberg and Yuichiro Kamada*

First Version: January 29, 2011; This Version: January 12, 2016

Abstract

In many laboratory experiments, different subjects in the same player role have different beliefs and play differently. To explore the impact of these heterogeneous beliefs, along with the idea that subjects use their information about other players’ payoffs, we define rationalizable partition-confirmed equilibrium (RPCE). We provide several examples to highlight the impact of heterogeneous beliefs, and show how mixed strategies can correspond to heterogeneous play in a large population. We also show any heterogeneous-belief RPCE can be approximated by a RPCE in a model where every agent in a large pool is a separate player.
1 Introduction

Learning from repeated observations can lead play in a game to approximate a form of self-confirming equilibrium, in which the strategies used are best responses to possibly incorrect beliefs about play that are not disconfirmed by the players’ observations. Of course, the set of such beliefs depends on what players observe when the game is played, and in some cases of interest players do not observe the exact terminal node, but only a coarser partition of them, such as when bidders in an auction do not observe the losing bids. Moreover, experimental data frequently suggests that subjects’ beliefs are heterogeneous, in the sense that different subjects in the same player role have different beliefs about the play of the subjects in other player roles.\(^1\) Finally, the data shows that subjects play differently when they are informed of opponents’ payoff functions than when they are not.\(^2\) To model these facts, we develop and analyze heterogeneous rationalizable partition-confirmed equilibrium (heterogeneous RPCE).

We do not develop an explicit learning theory here, but the model we develop is motivated by the idea that there is a large number of ex-ante identical agents in each player role, and that the agents interact anonymously, as in the Bayesian learning model of Fudenberg and Levine (1993b).\(^3\) Each period all agents in all player roles are randomly matched, so that one agent from each player role participates in each match. There are many models of this kind, depending on what information is revealed at the end of each round of play. In the information-sharing model, all agents in the same player role pool their information about what they observe after each round of play, so that in the

---

\(^1\)See e.g. the discussion of the best-shot, centipede, and ultimatum games in Fudenberg and Levine (1997). Fudenberg and Levine (1993a) introduced the distinction between unitary and heterogeneous beliefs in self-confirming equilibrium; Battigalli et al. (2014) allow heterogeneous beliefs in their extension to “model uncertainty.”

\(^2\)See for example Prasnikar and Roth (1992).

\(^3\)In Fudenberg and Levine (1993b) there is a unit mass of agents in each player role. In finite populations without identified player roles, each subject faces a slightly different distribution of opponents’ play, as subjects do not play themselves. Fudenberg and Takahashi (2011) provide conditions under which this difference is unimportant for the long-run outcome of learning in one-shot static games.
steady state they all have the same belief about the strategies of the other players. This leads to rationalizable partition-confirmed equilibrium with unitary beliefs, which we studied in Fudenberg and Kamada (2014) (hereafter “FK”). In the personal-information model, each agent observes and learns only the play in her own match, and no information sharing takes place. This is the treatment most frequently used in game theory experiments. It allows different agents in the same player role to maintain different beliefs, even after many iterations of the game, and even when the agents are identical ex ante, and provides a foundation for the sort of endogenous heterogeneity we consider here.

To see how heterogeneity in beliefs can matter, consider the three-player game in Figure 1.

![Figure 1: The agent, seller, and buyer are denoted players 1, 2, and 3, respectively.](image)

Here there are potential agents who facilitate trades between sellers and buyers. Each potential agent decides whether she enters the market or stays out; if she stays out, the game ends with no trade. If the agent enters, the
involved seller and buyer play a coordination game, where the efficient and inefficient outcomes correspond to the possible outcomes of an unmodelled process of negotiation. The personal-information model has a steady state in which some potential agents stay out of the market and the others enter, while all of sellers and buyers play efficient negotiations. Although staying out is not a best response, the agents can choose it if they believe the negotiations would be inefficient, and this belief will not be falsified by their observations. This is a heterogeneous self-confirming equilibrium, but it is not the outcome of a self-confirming equilibrium with unitary beliefs. This is because the aggregate play of the agents corresponds to a mixed distribution, yet if the agents pooled their information they would not be indifferent between the actions in the distribution’s support.

In this example player 1’s aggregate play corresponds to a mixed distribution. This is not the only way that heterogeneity of beliefs can make a difference. Consider the following situation: Investors decide whether to attend a business event, and entrepreneurs simultaneously decide whether to prepare materials to solicit investments. This preparation must be done before the meeting, and any entrepreneur who does prepare will then make a solicitation. Each investor derives a positive benefit from coming to the event, but this is outweighed by the cost if she is approached by an entrepreneur who solicits money, while entrepreneurs only want to attend if it is sufficiently likely they can talk with an investor. The payoff structure is shown in Figure 2.

\[
\begin{array}{c|cc}
\text{Investor} & \text{Solicit} & \text{Don't} \\
\hline
\text{Attend} & -1, 1 & 1, 0 \\
\text{Out} & 0, -1 & 0, 0 \\
\end{array}
\]

Figure 2
Note that the unique Nash equilibrium here is for both players to randomize \((1/2, 1/2)\). Now suppose that entrepreneurs always observe the investor’s action, but that an investor who stays Out does not observe if the entrepreneur solicits. Here, the profile \((Out, Don't)\) cannot be supported with unitary beliefs, as for the investor to stay out she has to expect a positive probability that the entrepreneur solicits, but this is not a best response to Out for the entrepreneur, which contradicts the assumption that the investor knows the entrepreneur is rational. With heterogeneous beliefs, on the other hand, it is not obvious why the outcome \((Out, Don't)\) should be rejected. To see why, note that if all agents in the role of investors think that the overall distribution of play corresponds to the Nash equilibrium of the game, these agents will be indifferent, and absent any information to the contrary all of the entrepreneurs could stay home even though none of the investors solicit.

The effect of heterogeneous beliefs is even starker in the game in Figure 3.

![Game Diagram](image)

Figure 3: The tax attorney, IRS agent, and tax evader are denoted players 1, 2, and 3, respectively.
Here, Nature first chooses Good or Bad. If it chooses Bad, then a tax attorney (player 1) prepares a tax return, which can be either Safe or Risky. Risky results in auditing by an IRS agent (player 2), and depending on the agent’s effort level, the attorney is either rewarded by the tax evader (player 3) or punished. If the attorney chooses Safe, the return will not be audited, and then the tax evader has a choice of staying with the attorney (Stay) or firing him (Fire). Nature’s choice of Good represents the situation in which the person who is audited has filed her tax return sincerely. The IRS agent, who does not know if the return is good or bad, would like to exert effort (E) in auditing if and only if it faces the evader, and otherwise prefers to not exert effort (N). The dotted circle connecting the payoffs of the attorney means that if the file is good, then the attorney does not observe what the IRS agent has chosen, as irrespective of the agent’s effort, the auditing would not result in punishment:

With unitary beliefs, it is not possible for the attorney to play Safe with probability 1. To see this, note that if she played Safe with probability 1 then she would know that whenever the IRS agent moves the IRS agent would know that Nature gave him the move, but then the agent should play N. Thus the attorney should expect the payoff of 2 from playing Risky, which dominates Safe.

However, with heterogeneous beliefs the attorney can play Safe with probability 1. Roughly, if each attorney thinks that all other attorneys play Risky, she has to infer each IRS agent assigns probability about .5 to each node, and this implies that the IRS agent must play E. But then if the evaders Stay, playing Safe is a best response. And an attorney can believe that other attorneys think Risky is a best response by supposing these other agents believe all the evaders play Fire.

We first lay out our model, then use it to analyze these and other examples with more rigor. We then show how heterogeneous play by a continuum of agents permits the “purification” of mixed strategy equilibria. That is, any outcome of a heterogeneous RPCE is the outcome of a heterogeneous RPCE in which all agents use pure strategies and believe that all other agents use
pure strategies as well. Finally, we relate the heterogenous RPCE of a given
game to the unitary RPCE of a larger “anonymous-matching game” in which
each of the agents in a given player role is viewed as a distinct player. Because
we assume that this larger game has a finite number of agents in each role,
the result here is not quite an equivalence, but involves some approximations
which vanish as the number of agents grows large.

2 Model and Notation

The game tree consists of a finite set $X$, with terminal nodes denoted by
$z \in Z \subseteq X$. The initial node corresponds to Nature’s move, if any. The set of
Nature’s actions is $A_N$. The distribution over Nature’s actions is known to all
players. The set of players is $I = \{1, \ldots, |I|\}$. $H_i$ is the collection of player $i$’s
information sets, with $H = \bigcup_{i \in I} H_i$ and $H_{-i} = H \setminus H_i$. Let $A(h)$ be the set of
available actions at $h \in H$, $A_i = \bigcup_{h \in H_i} A(h)$, $A = \times_{i \in I} A_i$ and $A_{-i} = \times_{j \neq i} A_j$.

For each $z \in Z$, player $i$’s payoff is $u_i(z)$. The information each player
observes at the end of each round of play is captured by a terminal node
partition $P_i$ that is a partition of $Z$, where we require that $u_i(z) = u_i(z')$ if
terminal nodes $z$ and $z'$ are in the same cell of $P_i$. We let $P = \{P_i\}_{i \in I}$ denote
the collection of the partitions.

Player $i$’s behavioral strategy $\pi_i$ is a map from $H_i$ to probability distribu-
tions over actions, satisfying $\pi_i(h) \in \Delta(A(h))$ for each $h \in H_i$. The set of
all behavioral strategies for $i$ is $\Pi_i$, and the set of behavioral strategy profiles
is $\Pi = \times_{i \in I} \Pi_i$. Let $\Pi_{-i} = \times_{j \neq i} \Pi_j$ with typical element $\pi_{-i}$. For $\pi \in \Pi$ and
$\pi_i \in \Pi_i$, $H(\pi)$ and $H(\pi_i)$ denote the information sets reached with positive
probability given $\pi$ and $(\pi_i, \pi_{-i})$, respectively, where $\pi_{-i}$ is any completely
mixed behavioral strategy.

Let $d(\pi)(z)$ be the probability of reaching $z \in Z$ given $\pi$, and let $D_i(\pi)(P_i^l) = \sum_{z \in P_i^l} d(\pi)(z)$ for each cell $P_i^l$ of player $i$’s partition. We assume that the ex-
tensive form has perfect recall in the usual sense, and extend perfect recall
to terminal node partitions by requiring that two terminal nodes must be in
different cells of $P_i$ if they correspond to different actions by player $i$. If every
terminal node is in a different cell of $P_i$, the partition $P_i$ is said to be discrete. If the cell $i$ observes depends only on $i$’s actions, the partition is called trivial.

For most of the paper we restrict attention to “generalized one-move games,” in which for any path of pure actions each player moves at most once, and for each $i$, there is no tuple $(a, a', a'', \bar{\pi}_{-i}, \bar{\pi}_{-i}, h)$, with $a, a', a'' \in A_N$, $a \neq a'$, $\bar{\pi}_{-i}, \bar{\pi}_{-i} \in \Pi_{-i}$ and $h \in H_i$, such that $h$ is reached with positive probability under both $(a, \bar{\pi}_{-i})$ and $(a', \bar{\pi}_{-i})$, while $h$ is reached with probability zero under $(a'', \bar{\pi}_{-i})$. This restriction lets us neglect complications that would arise in specifying assessments at off-path information sets.\footnote{This is a generalization of the “one-move games” defined in FK.}

We use a slightly more general class of games to relate the heterogeneous and unitary solution concepts, as in those games Nature’s move determines which agents are selected to play.

Player $i$’s belief is denoted $\gamma_i \in [\times_{h \in H_i} \Delta(h)] \times \Pi$, which includes her assessment over nodes at her information sets as well as her belief about the overall distribution of strategies. We denote the second element of $\gamma_i$ by $\pi(\gamma_i)$, and let $\pi_{-i}(\gamma_i)$ denote the corresponding strategies of players other than $i$. Note that we suppose that the belief about strategies is a point mass on a single behavior strategy profile, as opposed to a probability distribution over strategy profiles, which implicitly requires that the agents in the role of player $i$ all believe that the play of players $j$ and $k$ is independent.\footnote{We allowed for beliefs to be possibly correlated distributions on $\Pi$ in FK. Here we restrict to independence to focus on the new issues that arise with heterogeneity.}

To model the idea that players are reasoning about the beliefs and play of others, we use versions $v_i$ of player $i$. We index these versions by integers $k$, and let $V_i$ denote the set of versions of player $i$; for simplicity we assume that each $V_i$ is finite. Each version $v_i^k$ of player $i$ consists of a strategy $\pi_i^k \in \Pi_i$ and a conjecture $q_i^k \in \times_{j \in I} \Delta(V_j)$ about the distribution of versions in the population.

Not all of these versions need actually be present in the population. We track the shares of the versions that are objectively present with the share function $\phi = (\phi_i)_{i \in I}$, where each $\phi_i \in \Delta(V_i)$ specifies the fractions of the
population of player $i$ that are each $v^k_i$; version $v^k_i$ is called an “actual version” if $\phi_i(v^k_i) > 0$, and a “hypothetical version” otherwise. Hypothetical versions are the ones that some players think might be present but are not.

Next, we show how a belief model induces a behavior strategy profile $\pi$ that describes the aggregate play of the actual versions, and also induces, for each version $v^k_i$, the strategy profile that the version thinks describes actual play.

For each player $j$, define $\psi_j(\phi_j)$ for each $\phi_j$ by

$$\psi_j(\phi_j)(\hat{\pi}_j) = \sum_{\pi_j(v^k_j) = \hat{\pi}_j} \phi_j(v^k_j)$$

for each $\hat{\pi}_j$.

**Definition H1** A belief model $(V, \phi)$ induces actual play $\hat{\pi}_j$ if for all $j \in I$,

$$\hat{\pi}_j(h_j)(a) = \sum_{\pi'_j \in \text{supp}(\psi_j(\phi_j))} \psi_j(\phi_j)(\pi'_j) \cdot \pi'_j(h_j)(a).$$

We say that $(V, \phi)$ induces $\hat{\pi}_j$ for version $v^k_i \in V_i$ if $\hat{\pi}_j$ is constructed by replacing $\phi_j$ above by $q^k_i$.

### 3 Heterogeneous Rationalizable Partition-Confirmed Equilibrium

We begin with some preliminary definitions.

**Definition H2** Given a belief model $(V, \phi)$, we say $v^k_i$ is self-confirming with respect to $\pi^*$ if there exists $\hat{\pi}_{-i} \in \Pi_{-i}$ such that (i) $(V, \phi)$ induces $\hat{\pi}_j$ for version $v^k_i$ for each $j \neq i$ and (ii) $D_i(\pi^k_i, \hat{\pi}_i) = D_i(\pi^k_i, \pi^*_{-i})$.

**Definition H3** Given a belief model $(V, \phi)$, $v^k_i$ is observationally consistent if $q^k_i(\tilde{v}_j) > 0$ implies that there exists $\hat{\pi}_{-j} \in \Pi_{-j}$ such that (i) $(V, \phi)$ induces $\hat{\pi}_l$ for $v^k_i$ for each $l \neq j$ and (ii) $\tilde{v}_j$ is self-confirming with respect to $(\pi_j(\tilde{v}_j), \hat{\pi}_{-j})$.

It is important here to note that the observational consistency condition defined above restricts $v^k_i$’s belief about $i$’s strategies as well as her beliefs
about the strategies of the other players. This is needed because other agents in
the same player role may play differently from $v_i^k$.

We say that $\pi_i \in \Pi_i$ is a best response to $\gamma_i$ at $h \in H_i$ if the restriction of $\pi_i$ to the subtree starting at $h$ is optimal against the assessment at $h$ given by $\gamma_i$ and the continuation strategy of the opponents given by $\pi_{-i}(\gamma_i)$ in that subtree.

**Definition H4** $\pi^*$ is a heterogeneous rationalizable partition-confirmed equilibrium, or a heterogeneous RPCE, if there exists a heterogeneous belief model $(V, \phi)$ such that the following five conditions hold:

1. For each $i$, $(V, \phi)$ induces actual play $\pi^*_i$;
2. For all $v_k^i$, there exists $\gamma_i$ such that (i) $(V, \phi)$ induces $\pi_j(\gamma_i)$ for $v_k^i$ for each $j \neq i$ and (ii) $\pi_k^i$ is a best response to $\gamma_i$ at all $h \in H_i$;
3. $\phi_i(v_k^i) > 0$ implies $v_k^i$ is self-confirming with respect to $\pi^*$;
4. For each $i$, each $v_k^i \in V_i$ is observationally consistent.

Most of these conditions are straightforward generalizations of corresponding conditions for unitary RPCE. One significant change is in the self-confirming condition: In the unitary case, the self-confirming condition is imposed for those versions who have share 1 according to $\phi$. In our current context, multiple versions may exist with strictly positive shares, and in such a case we require that all such versions are self-confirming.

### 3.1 Brief Review of Unitary RPCE

Here we briefly review the definition of unitary RPCE. In this solution concept, a belief is $\mu_i \in \Delta(\Delta(h) \times \Pi_{-i}) \times \Pi_{-i}$. The coordinate for information set $h$ is denoted $(\mu_i)_h$. The second coordinate $\pi_{-i} \in \Pi_{-i}$ describes the strategy distribution the opponent believes she is facing and is denoted $b(\mu_i)$. Each $\mu_i$ is required to satisfy accordance, meaning the following:
Definition U0 A belief $\mu_i$ satisfies **accordance** if (i) $(\mu_i)_h$ is derived by Bayes rule if there exists $\pi_{-i}$ in the support of $b(\mu_i)$ such that $h$ is reachable under $\pi_{-i}$ and (ii) for all $h \in H_i$, if $(\mu_i)_h$ assigns positive probability to $\hat{\pi}_{-i}$, then there exists $\hat{\pi}_{-i} \in \text{supp}(b(\mu_i))$ such that $\hat{\pi}_{-i}(h') = \hat{\pi}_{-i}(h')$ for each $h'$ after $h$.\(^6\)

We say that $\pi_i \in \Pi_i$ is a best response to $\mu_i$ at $h \in H_i$ if the restriction of $\pi_i$ to the subtree starting at $h$ is optimal against the probability distribution over assessments and continuation strategies given by $\mu_i$.\(^7\)

A belief model $U := (U_j)_{j \in I}$ is a profile of finite sets, where $U_j = \{u^1_j, \ldots, u^K_j\}$ with $K_j$ being the number of elements in $U_j$. For each $j \in I$ and $k \in \{1, \ldots, K_j\}$ associate to $u^k_j$ a pair $(\pi_j^k, p_j^k)$, where $\pi_j^k \in \Pi_j$ and $p_j^k \in \Delta(\times_{j' \neq j} U_{j'})$, and write $u^k_j = (\pi_j^k, p_j^k)$. When there is no room for confusion, we omit superscripts that distinguish different versions in the same player role.

**Definition U1**

(a) Given a belief model $U$, $\pi^*$ is **generated** by a version profile $(\pi_i, p_i)_{i \in I} \in \times_{j \in I} U_j$ if for each $i$, $\pi_i = \pi^*_i$.

(b) A belief $\mu_i$ is **coherent** with a conjecture $p_i$ if $b(\mu_i)$ assigns probability $\sum_{\pi_{-i}(u_{-i}) = \tilde{\pi}_{-i}} p_i(u_{-i})$ to each $\tilde{\pi}_{-i} \in \Pi_{-i}$.

**Definition U2** Given a belief model $U$, version $u_i = (\pi_i, p_i)$ is **self-confirming** with respect to $\pi^*$ if $D_i(\pi_i, \pi_{-i}(u_{-i})) = D_i(\pi_i, \pi^*_{-i})$ for all $u_{-i}$ in the support of $p_i$.

**Definition U3** Given a belief model $U$, version $u_i = (\pi_i, p_i)$ is **observationally consistent** if $p_i(\tilde{u}_{-i}) > 0$ implies, for each $j \neq i$, $\tilde{u}_j$ is self-confirming with respect to $\pi(u_i, \tilde{u}_{-i})$.

Using these notions, we define unitary rationalizable partition-confirmed equilibrium as follows:

\(^6\)Claim 1 in Appendix A shows that accordance is implied by independent beliefs adapted to the unitary model where we assume that only a single strategy profile is in the support of both $b(\mu_i)$ and $(\mu_i)_h$ for every information set $h$ of player $i$.

\(^7\)This is essentially the same definition as above, the only difference is that the domain of the best responses has been changed.
Definition U4 \( \pi^* \) is a **unitary rationalizable partition-confirmed equilibrium** if there exist a belief model \( U \) and an actual version profile \( u^* \) such that the following conditions hold:

1. \( \pi^* \) is generated by \( u^* \).
2. For each \( i \) and \( u_i = (\pi_i, p_i) \), there exists \( \mu_i \) such that (i) \( \mu_i \) is coherent with \( p_i \) and (ii) \( \pi_i \) is a best response to \( \mu_i \) at all \( h \in H_i \).
3. For all \( i \), \( u_i^* \) is self-confirming with respect to \( \pi^* \).
4. For all \( i \) and \( u_i \), \( u_i \) is observationally consistent.

There are two main differences in the definitions of versions in the unitary and heterogeneous belief models. First, in unitary belief models, conjectures do not specify a probability measure over the player’s own versions. Second, in the unitary model players are sure that only one actual version exists for each player role, but unsure which one is actual. In the heterogeneous model they assign probability one to a single version distribution for each player role. Thus, in the heterogeneous model, a conjecture of \((\frac{1}{2}v^k_2 + \frac{1}{2}v^k_3, \frac{1}{2}v^l_2 + \frac{1}{2}v^l_3)\) means that 1/2 of the player 2’s are \( v^k_2 \) and not that there is probability 1/2 that all of them are \( v^k_2 \), which is allowed in the unitary model.

### 4 Examples

In this section we illustrate heterogeneous RPCE with several examples. We first revisit Examples 1-3 to formalize the arguments provided there.

**Example 1 (Mixed Equilibrium and Heterogeneous Beliefs)**

We revisit the game of Figure 1 to explain why \( ((\frac{1}{2}In_1, \frac{1}{2}Out_1), U_2, U_3) \) is not a unitary RPCE but is a heterogeneous RPCE.

To see that it is not a unitary RPCE, note that if it were, then by the self-confirming condition the actual version of player 1 must believe that player
2 and player 3 play \((U_2, U_3)\) with probability one. But given this belief the only best response is to play action \(In_1\) with probability one, so 1’s strategy contradicts the best response condition.

However the profile is a heterogeneous RPCE. To see this, consider the following belief model:

\[
V_1 = \{v_1^1, v_1^2\} \quad \text{with} \quad v_1^1 = (Out_1, (v_1^1, v_2^1, v_3^2)), \quad v_1^2 = (In_1, (\frac{1}{2}v_1^1 + \frac{1}{2}v_1^2, v_2^1, v_3^1));
\]

\[
V_2 = \{v_2^1, v_2^2\} \quad \text{with} \quad v_2^1 = (U_2, (\frac{1}{2}v_1^1 + \frac{1}{2}v_1^2, v_2^1, v_3^1)), \quad v_2^2 = (D_2, (v_1^1, v_2^2, v_3^2));
\]

\[
V_3 = \{v_3^1, v_3^2\} \quad \text{with} \quad v_3^1 = (U_3, (\frac{1}{2}v_1^1 + \frac{1}{2}v_1^2, v_2^1, v_3^2)), \quad v_3^2 = (D_3, (v_1^1, v_2^2, v_3^2));
\]

\[
\phi_1(v_1^1) = \phi_1(v_1^2) = \frac{1}{2}, \quad \phi_2(v_2^1) = 1, \quad \phi_3(v_3^1) = 1.
\]

It is easy to check that the RPCE conditions hold (note that \(v_2^2\) and \(v_3^2\) must believe that all player 1’s play \(Out_1\), because otherwise \(v_1^1\)’s observational consistency would be violated).

**Example 2 (Investor-Entrepreneur)**

Here we revisit the investor-entrepreneur game of Figure 2. We first show that \((Out, Don’t)\) cannot be a unitary RPCE. To see this, suppose the contrary. Note that the best response condition implies that the actual version of player 1 has to assign a strictly positive probability to a version \(v_2'\) of player 2 that plays Solicit with strictly positive probability. But then observational consistency applied to the actual version of player 1 implies that the belief of \(v_2'\) assigns probability 1 to \(Out\), which would make Solicit strictly suboptimal.

To show that \((Out, Don’t)\) is a heterogeneous RPCE, consider the following belief model:

\[
V_1 = \{v_1^1, v_1^2\} \quad \text{with} \quad v_1^1 = (Out, (\frac{1}{2}v_1^1 + \frac{1}{2}v_1^2, \frac{1}{2}v_2^1, \frac{1}{2}v_2^2, \frac{1}{2}v_3^2)),
\]

\[
v_1^2 = (In, (\frac{1}{2}v_1^1 + \frac{1}{2}v_1^2, \frac{1}{2}v_2^1, \frac{1}{2}v_2^2, \frac{1}{2}v_3^2));
\]
\[ V_2 = \{v_1^2, v_2^2, v_3^2\} \quad \text{with} \quad v_1^1 = (\text{Don’t}, (\text{Don’t}, \text{Solicit})) \]

\[ v_2^2 = (\text{Don’t}, (\frac{1}{2}v_1^1 + \frac{1}{2}v_2^1, \frac{1}{2}v_2^2 + \frac{1}{2}v_3^2)), \quad v_3^3 = (\text{Solicit}, (\frac{1}{2}v_1^1 + \frac{1}{2}v_2^1, \frac{1}{2}v_2^2 + \frac{1}{2}v_3^3)); \]

\[ \phi_1(v_1^1) = 1, \phi_2(v_2^1) = 1. \]

Fudenberg and Levine (1993a) show by example that there are heterogeneous self-confirming equilibria that are not unitary self-confirming equilibrium. The profile they construct uses mixed strategies, and the mixing is necessary: If a strategy profile is a heterogeneous self-confirming equilibrium but is not a unitary self-confirming equilibrium, then it uses mixed strategies.

In contrast, in this example there is a heterogeneous RPCE in which the distribution of strategies generated by \( \phi \) is pure, yet the observed play cannot be the outcome of a unitary RPCE.

Example 3 (Heterogeneous RPCE with Pure Strategies)

Here we revisit the tax evasion example of Figure 3. To see that the profile \((\text{Safe}, N, \text{Stay})\) cannot be a unitary RPCE, suppose the contrary. Then the actual version of the attorney (player 1) must play \text{Safe}, so by observational consistency her conjecture assigns probability 1 to versions of the IRS agent (player 2) whose assessment assigns probability 1 to the left node in 2’s information set. By the best response condition these versions must play \text{N}. Then the coherent belief condition implies that the actual version of player 1 believes that 2 plays \text{N}, and by the best response condition she has to play \text{Risky} instead of \text{Safe} irrespective of her belief about the play by the tax evader (player 3).

To see that the profile is a heterogeneous RPCE, consider the following belief model:

\[ V_1 = \{v_1^1, v_1^2\} \quad \text{with} \quad v_1^1 = (\text{Safe}, (v_1^2, v_2^2, v_3^3)), \quad v_1^2 = (\text{Risky}, (v_1^2, v_2^2, v_3^3)); \]

\[ V_2 = \{v_2^1, v_2^2\} \quad \text{with} \quad v_2^1 = (N, (v_1^1, v_2^1, v_3^1)), \quad v_2^2 = (E, (v_1^2, v_2^2, v_3^3)); \]

\[ V_3 = \{v_3^1, v_3^2, v_3^3\} \quad \text{with} \quad v_3^1 = (\text{Stay}, (v_1^1, v_2^1, v_3^1)), \]

\[ v_3^2 = (N, (v_1^1, v_2^1, v_3^1)), \quad v_3^3 = (E, (v_1^2, v_2^2, v_3^3)). \]
\[ v_3^2 = (\text{Stay}, (v_1^2, v_2^2, v_3^2)), \quad v_3^3 = (\text{Fire}, (v_1^2, v_2^2, v_3^3)); \]
\[ \phi_1(v_1^1) = 1, \ \phi_2(v_2^1) = 1, \ \phi_3(v_3^1) = 1. \]

Notice that in this belief model, version \( v_1^2 \) has share 0, but each agent of version \( v_1^1 \) thinks that all other agents in his player role are version \( v_1^2 \). This is possible, because if version \( v_1^2 \) was an actual version, he could not observe 3’s play, so his belief about 3’s play can be arbitrary. Given that all other agents are playing Risky, \( v_1^1 \) infers 2 should be playing \( E \), and such a belief is “self-confirming” because \( v_1^1 \) does not observe 2’s choice due to the terminal node partition.\(^8\)

Note that players 1 and 2 have strict incentives to play the equilibrium actions, unlike in the heterogeneous RPCE in Example 2.

Note also that the construction here is different from that of Example 1, where each agent thinks that all other agents in the same role are playing in the same way as she does, while here each agent thinks that other agents in the same player role behave differently than herself. Example 7 in the Online Supplementary Appendix extends this idea to show that a heterogeneous RPCE can be different from a unitary RPCE because an actual version of one player role can conjecture that different versions in another player role play differently.

**Example 4 (Inferring the Play of Other Agents in the Same Role)**

\(^8\)Hence each agent in \( v_1^1 \) thinks that he has measure zero. This is not necessary here: the same conclusion applies if \( v_1^1 \) believes the share of \( v_1^1 \)'s is strictly less than 1/2. In Example 5, which has a weakly dominated strategy, it does matter that a version can think it has share 0.

\(^9\)Player 3 has three versions although she has two actions because we need two versions who play Stay: the actual version who observes Safe, and a hypothetical version who observes Risky, which is needed so that \( v_1^1 \) is observationally consistent.
Here we show how knowledge of the payoff functions and the observation structure can rule out heterogeneous beliefs when neither of these forces would do so on its own, as agents in a given player role may be able to use their observations to make inferences about the play of other agents in their own role. In the game in Figure 4, the terminal node partitions are discrete. One might conjecture that some player 2’s can play \textit{Out}$_2$ while some play \textit{In}$_2$ and some player 1’s play \textit{In}$_1$, as \textit{Out}$_2$ prevents player 2 from observing 3 and 4’s play. However, we claim that whenever a heterogeneous RPCE assigns strictly positive probability to \textit{In}$_1$, player 2 plays \textit{In}$_2$ with probability 1.

To see this, consider a heterogeneous RPCE such that 1 plays \textit{In}$_1$ with a strictly positive probability. Fix a belief model that rationalizes this hetero-
geneous RPCE and fix an actual version $v_2$ of player 2. We show that $v_2$ must play $I_{n_2}$ with probability 1 in this heterogeneous RPCE.

First, by the self-confirming condition, $v_2$’s conjecture assigns positive probability to a version $\bar{v}_1$ of player 1 that plays $I_{n_1}$ with positive probability. Suppose that $v_2$’s conjecture assigns probability zero to versions of player 2 that play $I_{n_2}$ with positive probability. Then, by observational consistency applied to $v_2$, $\bar{v}_1$ believes 2 plays $Out_2$ with probability 1. But this contradicts the best response condition for $\bar{v}_1$. Hence $v_2$’s conjecture must assign a positive probability to versions who play $I_{n_2}$ with positive probability. Pick one such version who plays $I_{n_2}$, and call it $\bar{v}_2$.

Since $\bar{v}_2$ must satisfy the best response condition, he must assign probability at least $\frac{5}{6}$ to $(L_3, L_4)$. Since $\bar{v}_2$ observes play by players 3 and 4, by observational consistency applied to $v_2$, this means that $v_2$’s belief assigns probability at least $\frac{5}{6}$ to $(L_3, L_4)$ as well. This in particular implies that $v_2$’s belief assigns probability at least $\frac{5}{6}$ to $L_3$. But $L_4$ is the unique best response to a strategy that plays $L_3$ with probability at least $\frac{5}{6}$ (given that player 4 is on the path), so observational consistency applied to $v_2$ and the best response condition for player 4 imply that $v_2$’s belief assigns probability 1 to $L_4$, and similarly, it assigns probability 1 to $L_3$. But then the best response condition for $v_2$ implies that she must play $I_{n_2}$ with probability 1.

Note that extensive-form rationalizability alone does not preclude heterogeneity, as all actions of all players are extensive-form rationalizable. As we show in the Online Supplementary Appendix, common knowledge of observation structure alone does not rule out heterogeneity either.

Example 5 (Heterogeneous RPCE with Dominated Strategies)
Our definition allows each version to believe that the aggregate play of her player role does not assign positive mass to her own strategy. For example, even if $v^i_k$ plays $L_i$, her belief may assign probability 1 to $R_i$. This reflects the premise that there is a continuum of agents in each player role and no one agent can change the aggregate distribution of play. This continuum model is meant to be an approximation of a large but finite population model. In Section 6, we formalize this idea of approximation by using $\epsilon$-self-confirming and $\epsilon$-observational consistency conditions, as opposed to the exact self-confirming and the observational consistency conditions. This example shows why some sort of approximate equilibrium notion is needed.

The game in Figure 5 has the same extensive form as in the game in Example 3, with a different payoff function for player 2. Notice that $R_2$ is weakly dominated.

We first show that 1 can play $R_1$ in a heterogeneous RPCE. To see this,
consider the following belief model:

\[ V_1 = \{v_1^1, v_1^2\} \quad \text{with} \quad v_1^1 = (R_1, (v_1^2, v_2^3)), \quad v_1^2 = (L_1, (v_1^2, v_2^2)) \]

\[ V_2 = \{v_2^1, v_2^2\} \quad \text{with} \quad v_2^1 = (L_2, (v_1^1, v_2^1, v_3^1)), \quad v_2^2 = (R_2, (v_1^2, v_2^2, v_3^2)) \]

\[ V_3 = \{v_3^1, v_3^2\} \quad \text{with} \quad v_3^1 = (L_3, (v_1^1, v_2^1, v_3^1)), \]

\[ v_3^2 = (L_3, (v_1^2, v_2^2, v_3^2)), \quad v_3^3 = (R_3, (v_1^2, v_2^2, v_3^3)) \]

\[ \phi_1(v_1^1) = 1, \quad \phi_2(v_2^1) = 1, \quad \phi_3(v_3^1) = 1. \]

Notice that in this belief model, the actual version \( v_1^1 \) of player 1 conjectures that version \( v_1^2 \) has share 1, which justifies his belief that player 2 is indifferent between two actions so can play a weakly dominated action \( R_2 \). One can check by inspection that all conditions in the definition of heterogeneous RPCE are met.

However, player 1 cannot play \( R_1 \) if we require that each version’s belief has to assign a positive weight to her own strategy. To see this, notice that if this condition were imposed, observational consistency and Bayes rule would imply that each version \( v_k^1 \) of player 1 assigns probability 1 to versions of player 2 whose assessments assign probability strictly less than \( \frac{1}{2} \) to the node that follows \( L_1 \). By the best response condition, these versions must play \( L_2 \). But then from condition 2(i) of Definition H4 \( v_k^1 \) would need to believe that 2 will play \( L_2 \) with probability 1, so that \( R_1 \) would give her a strictly smaller payoff than the maximal possible payoff from \( L_1 \), which contradicts the best response condition.

The point is that in a finite population model an agent’s own actions can give her information about an opponent’s belief and hence about their strategy, but such an inference is not captured by heterogeneous RPCE.
5 A “Purification” Result

In the heterogeneous model, the aggregate play of agents in each player role can correspond to a mixed (behavior) strategy. One standard interpretation of mixed strategies in equilibrium is that the mixing describes the aggregate play of a large population, with different agents in the same player role using different pure strategies. Here we show that this interpretation of mixed-strategy equilibrium also applies to heterogeneous RPCE with a continuum of agents in each player role, so that the shares \( \phi_i \) describe the mass of each population \( i \) whose play and conjectures correspond to the various versions. The continuum of agents allows \( \phi_i \) to take on any value between 0 and 1. In the next section we relate this continuum model to one with a large but finite population.

**Theorem 1** Any heterogeneous RPCE can be rationalized with a belief model in which all versions use pure strategies.

**Proof.** Fix a heterogeneous RPCE \( \pi^* \) and a belief model \( (V, \phi) \) that rationalizes it. Pick any version \( v^k_i = (\pi^k_i, q^k_i) \) in \( V \), let \( \sigma^k_i \) be a mixed strategy that induces \( \pi^k_i \),\(^{10}\) and suppose that \( \sigma_i \) assigns positive probability to \( K \) distinct pure strategies. We construct copies of version \( v^k_i \), each playing a distinct pure strategy in the support of \( \sigma^k_i \). The copy corresponding to pure strategy \( s_i \), denoted \( v^k_i(s_i) \), plays \( s_i \) and has the same belief as \( v^k_i \).

To construct the conjectures in the new belief model from the conjectures in the old one, we suppose that all of the copies corresponding to \( v^k_i \) have the same conjecture \( \bar{q}^k_i \), where \( \bar{q}^k_i(v^j_i(s_j)) = q^k_i(v^j_i) \cdot \sigma^j_i(s_j) \) for all \( v^j_i \in V_j \) and all \( s_j \in \text{supp}(\sigma^j_i) \).\(^{11}\) Finally, denoting the share function in the new belief model by \( \bar{\phi} \), we let \( \bar{\phi}((v^k_i(s_i)) = \phi(v^k_i) \cdot \sigma^k_i(s_i) \) for each \( s_i \in \text{supp}(\sigma^k_i) \).

It is straightforward to check that with this construction the new belief model rationalizes the original heterogeneous RPCE. \( \blacksquare \)

\(^{10}\)This mixed strategy exists from Kuhn’s theorem; see for example the proof of Theorem 4 in Fudenberg and Levine (1993a).

\(^{11}\)With a slight abuse of notation, we denote by \( q^k_i(v^j_i) \) the marginal of \( q^k_i \) on \( v^j_i \).
6 Anonymous-Matching Games in Large Finite Populations

The interpretation of heterogeneous beliefs and play is that there are many agents in each player role. An alternative way of thinking of such situations is that every agent is a “player,” but each period only a subset of the agents get to actually play; the agents who are not playing do not receive any feedback on what happened that period. In this way, we can identify an anonymous-matching game with any given extensive form. To do this, we view each of the agent $k$’s in the role of player $i$ as distinct players, so the anonymous-matching game has as many players as the original model has agents. Each period Nature picks $|I|$ players to anonymously participate in the game, where $|I|$ is the number of player roles in the original extensive form, and only one player is picked from each of the respective groups.

We will show that each heterogeneous RPCE of a small extensive-form game is an “approximate” unitary RPCE in an anonymous-matching game, where the approximation becomes arbitrarily close as the population of the anonymous-matching game becomes large.

6.1 Anonymous-Matching Games

Formally, given an extensive-form game $\Gamma$ with a set of players $I = \{1, ..., |I|\}$ and the terminal node partitions $P = (P_1, \ldots, P_{|I|})$, we define an anonymous-matching game of $\Gamma$ parameterized by a positive integer $T$ defined below, denoted $Y(\Gamma, T)$, as follows$^{12}$:

1. The set of players is $J := \bigcup_{i \in I} J_i$, with $J_i := \{(i, 1), \ldots, (i, T)\}$, where $T$ is a positive integer.

2. Nature $N$ moves at the initial node, choosing $|I|$ players who will move at subsequent nodes. For each $i \in I$, a unique player is chosen from $J_i$

---

$^{12}$We assume there is the same number of players in each player role; none of our results hinges on this assumption.
independently, according to the uniform distribution over $J_i$. Let the chosen player for each $i \in I$ be $(i, r_i)$.

3. The chosen players, $((1, r_1), (2, r_2), \ldots, (n, r_n))$, play $\Gamma$, without knowing the identity of the opponents. Unchosen players receive the constant payoffs of 0. Formally,

(a) Each node of $Y(\Gamma, T)$ is denoted $(x, (i, w_i)_{i \in I})$, where $x$ is an element of $X$ of $\Gamma$ and $w_i$ is the index of the agent in player role $i$ who “plays” in the game that contains the node.

(b) For each player $(i, w_i) \in J_i$, nodes $(x, (j, w_j)_{j \in I})$ and $(x', ((i, w_i), (j, w'_j)_{j \neq i}))$ are in the same information set if and only if $x$ and $x'$ are in the same information set of player $i$ in $\Gamma$ (This formalizes the idea that the identity of the matched agents cannot be observed).

(c) For any $(i, w_i)_{i \in I}$, actions available at an information set that includes $(x, (i, w_i)_{i \in I})$ is the same as the actions available at an information set that includes $x$ in $\Gamma$.

(d) The payoff function is such that if a player in $J_i$ is chosen and an action profile $a$ of the chosen players (which lies in $A$) is realized, she receives a payoff identical to $u_i(z)$ where the sequence of actions $a$ leads to the terminal node $z$ in $\Gamma$. If a player is not chosen, she receives the payoff of 0.

(e) The terminal node partition is such that if a player is not chosen then she does not observe anything (except the fact that she was not chosen). If a player $(i, r_i) \in J_i$ is chosen and a terminal node $(z, (j, r_j)_{j \in I})$ is reached, all she knows is that some node $(z', (r_i, w'_{-i}))$ for some $z'$ and $w'_{-i} \in \times_{j \neq i} J_j$ is reached, where $z'$ and $z$ are in the same partition cell of $P_i$ in $\Gamma$ (In particular, she does not know the identity of the opponents).

6.2 Unitary $\epsilon$-RPCE

Hereafter, we assume that $\mu_i$ satisfies the following condition:
Definition U5 A belief $\mu_i$ satisfies **convex structurally-consistent accordance** if it satisfies the following three conditions:

1. $\mu_i$ satisfies accordance.

2. For each $h \in H_i$ and each $(a_i, \pi_{-i}) \in \text{supp}((\mu_i)_h)$, there exists a probability distribution $\gamma \in \Delta(\Pi_{-i})$ such that (i) there exists $\hat{\pi}_{-i} \in \text{supp}(\gamma)$ such that $h$ is reachable under $\hat{\pi}_{-i}$, and (ii) the assessment $a_i$ at $h$ is derived by Bayes rule under $\gamma$.

In anonymous-matching games, Nature’s move determines which agents get to play. The second condition in the definition imposes a restriction on the probability distribution over the agents chosen by Nature at each off-path information set $h$: we require that this probability distribution does not change even after a deviation that leads to $h$ (note that the deviator does not move at $h$ because we still assume that each player moves only once at each path of the extensive form). The reason we allow for a distribution $\gamma$ of strategies here is analogous to the argument for convex structural consistency in Kreps and Ramey (1987): the stronger condition that one single profile generates the beliefs is not compatible with Kreps-Wilson’s (1982) consistency.

Let $||\cdot||$ denote the supremum norm. We say that $\pi_i$ represents $(\pi_{i,1}, \ldots, \pi_{i,T})$ if, for each $h_i \in H_i$ and action $a$’s available there, $\pi(h_i)(a) = \frac{1}{T} \sum_{j=1}^{T} \pi_{i,j}(h_i)(a)$. We say that $\pi_i \epsilon$-represents $(\pi_{i,1}, \ldots, \pi_{i,T})$ if there is $\pi_i'$ such that $\pi_i'$ represents $(\pi_{i,1}, \ldots, \pi_{i,T})$ and $||\pi_i - \pi_i'|| < \epsilon$.

**Definition U2(\epsilon)** Given a belief model $U$, version $u_i = (\pi_i, p_i)$ is $\epsilon$-self-confirming with respect to $\pi^*$ if $||D_i(\pi_i, \pi_{-i}(u_{-i})) - D_i(\pi_i, \pi^*_{-i})|| < \epsilon$ for all $u_{-i}$ in the support of $p_i$.

**Definition U3(\epsilon)** Given a belief model $U$, version $u_i = (\pi_i, p_i)$ is $\epsilon$-observationally consistent if $p_i(\tilde{u}_{-i}) > 0$ implies, for each $j \neq i$, $\tilde{u}_j$ is $\epsilon$-self-confirming with respect to $\pi(u_i, \tilde{u}_{-i})$.

Using these notions, we define unitary $\epsilon$-rationalizable partition-confirmed equilibrium.
Definition U4(\(\epsilon\)) \(\pi^*\) is a unitary \(\epsilon\)-rationalizable partition-confirmed equilibrium (unitary \(\epsilon\)-RPCE) if there exist a belief model \(U\) and an actual version profile \(u^*\) such that the following conditions hold:

1. \(\pi^*\) is generated by \(u^*\).
2. For each \(i\) and \(u_i = (\pi_i, p_i)\), there exists \(\mu_i\) such that (i) \(\mu_i\) is coherent with \(p_i\) and (ii) \(\pi_i\) is a best response to \(\mu_i\) at all \(h \in H_i\).
3. For all \(i\), \(u_i^*\) is \(\epsilon\)-self-confirming with respect to \(\pi^*\).
4. For all \(i\) and \(u_i\), \(u_i\) is \(\epsilon\)-observationally consistent.

### 6.3 The Equivalence Theorem

**Theorem 2** For any \(\epsilon > 0\), \(\Gamma\), and a heterogeneous RPCE \(\pi^*\) of \(\Gamma\), there exist \(T\) and a pure unitary \(\epsilon\)-RPCE \(\pi^{**}\) of \(Y(\Gamma, T)\) such that for each \(i \in I\), \(\pi_i^*\) \(\epsilon\)-represents \((\pi^{**}_{(i,1)}, \ldots, \pi^{**}_{(i,T)})\).

The proof is provided in the appendix. It is complicated because we aim to achieve the exact best response, as opposed to \(\epsilon\)-best response. For example suppose that in the original heterogeneous belief model version \(v^k_1\) assigns probability \(\frac{1}{\sqrt{2}} \approx .707\) to action \(A\) of player 2 and the remaining probability to action \(B\), and that this makes \(v^k_1\) indifferent between her actions \(U\) and \(D\). Suppose also that mixing between actions \(A\) and \(B\) cannot be a best response for player 2, so \(v^k_1\)'s conjecture must assign positive probability only to versions of player 2 who use pure strategies.\(^{13}\) In this case there are no share functions generated by a finite number of agents that make her believe in the probability distribution \((\frac{1}{\sqrt{2}}, 1 - \frac{1}{\sqrt{2}})\), as no version that is assigned positive probability by a share function can play a mixed strategy.

One way to get around this problem would be to relax the requirement that each agent in a player role is equally likely to play the anonymous-matching

\(^{13}\)Such a situation is possible in a RPCE for example when players 3 and 4 play a coordination game after 2 moves, 2’s terminal node partition lets him observe the outcome of the coordination game only when he plays \(A\), and player 2 has a strict incentive to play one of actions \(A\) and \(B\) given each Nash equilibrium of the coordination game.
game. If we consider the situation with \( J_2 = 2 \) and Nature chooses one agent with probability \( \frac{1}{\sqrt{2}} \) and the other agent with the remaining probability, then mixing between \( U \) and \( D \) can be the exact best response. This approach generalizes: Theorem 2 holds if we allow the probability distribution over agents in the anonymous-matching game to depend on the unitary RPCE that is being replicated. We do not state this version of the result formally, as we do not find it satisfactory to vary the probability distribution over agents to match the target equilibrium.\(^{14}\)

Our method to overcome the problem with irrational probabilities for some actions is as follows. Let \( \tilde{v}_{(1,j)}^k \) be the version in the constructed unitary belief model who corresponds to \( v_{1}^k \) in the original heterogeneous belief model. We construct a conjecture such that \( \tilde{v}_{(1,j)}^k \) is not certain about what the share functions are. For example, if \( T = 100 \) then we let \( \tilde{v}_{(1,j)}^k \)'s conjecture assign probability 1 to the event that 70 agents are the versions who play \( A \) and 29 agents are the versions who play \( B \), assign probability \( \frac{1}{\sqrt{2}} - \frac{70}{100} \) to the event that the remaining one agent is the version who plays \( A \), and assign the remaining probability to the event that the remaining one agent is the version who plays \( B \). We construct the belief so that coherency holds. With this construction any point in the belief of \( \tilde{v}_{(1,j)}^k \) has a belief such that all points in the support is close to the corresponding point in the support of \( v_{1}^k \) (because 99 agents play deterministically) and the belief is essentially unchanged so the mixing between \( U \) and \( D \) is still a best response (because we allow the remaining one agent to be either one of the two possible versions with the probability computed from the original mixing probability of player 2). There is more subtlety in making sure the best-response condition holds also at zero-probability information sets, which we will detail in the proof.

In the Online Appendix, we discuss our choice of approximation criterion used in defining \( \epsilon \)-observational consistency, and explain the implications of an alternative.

\(^{14}\)Theorem 2 applies to any probability distribution over agents in each player role with the property that each agent is selected with probability \( o(1) \). For example, this probability can be \( O(\frac{1}{T}) \).
7 Conclusion

This paper has developed an extension of RPCE to allow for heterogeneous beliefs, both on the part of the agents who are objectively present, and also in the “versions” that represent mental states agents think other agents can have. This extension allows the model to fit experimental evidence of heterogeneous beliefs, and it also permits RPCE to be restricted to pure strategies without loss of generality. The paper explored the impact of heterogeneous beliefs in various examples. It also showed how heterogeneous RPCE relates to the unitary RPCE of a larger anonymous-matching game with many agents in each player role.

References

A Independence and Accordance

Recall that unitary RPCE is only defined for 1-move games. In that solution concept, a belief \( \mu_i \) belongs to the space \( [\times h \in H_i \Delta(\Delta(h) \times \Pi_{-i})] \times \Delta(\Pi_{-i}) \). We denote \( (\mu_i)_h \) the coordinate of \( \mu_i \) that corresponds to \( h \), and \( b(\mu_i) \) the last coordinate that does not correspond to any particular information sets.

Although we do not use it in the next claim, keep in mind that the space of the beliefs in the heterogeneous model is \( [\times h \in H_i \Delta(h)] \times \Delta(\Pi) \).

**Claim 1** Suppose that under a belief \( \mu_i \), \( b(\mu_i) \) assigns probability one to a single strategy profile for \( i \)'s opponents, \( \pi^*_{-i} \). Suppose also that for every \( h \in H_i \), \( (\mu_i)_h \) assigns probability one to a single assessment-strategy profile pair such that the strategy profile to which probability one is assigned is \( \pi^*_{-i} \). Then, accordance holds.

**Proof.** Accordance requires two conditions. We check them one by one.

The first condition of accordance requires that \( (\mu_i)_h \) is derived by Bayes rule if there exists \( \pi_{-i} \) in the support of \( b(\mu_i) \) such that \( h \) is reachable under \( \pi_{-i} \). Since \( b(\mu_i) \) and \( (\mu_i)_h \) for each \( h \) assigns probability 1 to the same strategy profile for \( -i \), this part is holds.

The second condition requires that for each \( h \in H_i \), if \( (\mu_i)_h \) assigns positive probability to \( \tilde{\pi}_{-i} \), then there exists \( \tilde{\pi}_{-i} \in \text{supp}(b(\mu_i)) \) such that \( \tilde{\pi}_{-i}(h') = \tilde{\pi}_{-i}(h') \) for all \( h' \) after \( h \).

Now, \( (\mu_i)_h \) assigns positive probability only to \( \pi^*_{-i} \). Also, \( \pi^*_{-i} \) is in the support of \( b(\mu_i) \). Thus we can always take \( \tilde{\pi}_{-i} = \pi^*_{-i} \) to satisfy the equality.

B Proof of Theorem 2

**Proof.**

Fix \( \epsilon > 0 \) and a heterogeneous RPCE of \( \Gamma, \pi^* \). By Theorem 1 there exists a belief model \((V, \phi)\) that rationalizes \( \pi^* \) such that all versions in the belief model use pure strategies. Fix one such belief model. For each \( i \) and \( k \), let

\[27\]
\( \gamma_i^k = (a_i^{[i,k]}, \pi_i^{[i,k]} ) \) be the belief of \( u_i^k \) used in condition 2 of the definition of heterogeneous RPCE. Pick an integer \( T \) such that \( T > \max \{ 2^{[\max_{i \in I} l(V_i)](#A)^2}, \frac{1}{\epsilon} \} \), where

\[
G = \min_{i \in I} \left( \min_{k \in \{1, \ldots, |V_i| \}} \left( \max_{\pi_i \in \Pi_i} \min_{z \in Z(\pi_i, \pi_i^{[i,k]})} p(\pi_i, \pi_i^{[i,k]})(z) \right) \right),
\]

\( p(\pi)(z) \) is the probability that \( z \in Z \) is reached under \( \pi \), and \( Z(\pi) \) is the set of terminal nodes \( z \) such that \( p(\pi)(z) > 0 \). To prove the claim we need to construct a belief model \( U \) and an actual version profile \( u^* \) for the game \( Y(\Gamma, T) \) such that there is a pure unitary \( \epsilon \)-RPCE \( \pi^{**} \) of \( Y(\Gamma, T) \) where for each \( i \in I \), \( \pi_i^* \) \( \epsilon \)-represents \( (\pi_{i,1}^{**}), \ldots, \pi_{i,T}^{**}) \).

**a) Constructing the belief model**

For each \( i \in I \) and each \( (i, j) \in J_i \), define \( U_{(i,j)} = \{ \tilde{u}_{(i,j)}(v_i^k) | v_i^k \in V_i \} \), where \( \tilde{u}_{(i,j)}(v_i^k) = (\tilde{\pi}_{(i,j)}^k, \tilde{p}_{(i,j)}^k) \) and we define \( \tilde{\pi}_{(i,j)}^k \) and \( \tilde{p}_{(i,j)}^k \) in what follows. Below we simply denote \( \tilde{u}_{(i,j)}(v_i^k) \) by \( u_{(i,j)}^k \).

First, \( \tilde{\pi}_{(i,j)}^k = \pi_i^{(k)} \).\(^{15}\) Note this is a pure strategy.

Second, we let \( \tilde{p}_{(i,j)}^k \) be independent, and abuse notation to denote by \( \tilde{p}_{(i,j)}^k (u_{(n,m)}) \) the probability assigned to \( u_{(n,m)} \) by the conjecture of \( v_i^k \). That is, \( \tilde{p}_{(i,j)}^k ((\tilde{u}_{(n,m)}(n,m) \neq (i,j)) = \prod_{(n,m) \neq (i,j)} \tilde{p}_{(i,j)}^k (\tilde{u}_{(n,m)}) \) for each \((\tilde{u}_{(n,m)}(n,m) \neq (i,j)) \in U_{-(i,j)} \). Similarly, we abuse notation to write \( q_i^k(v_n^m) \) (recall that \( q_i^k \) is necessarily independent by definition).

Below we specify \( \tilde{p}_{(i,j)}^k \) in the way we described in the example of 100 agents before this proof. In that method, there are 29 agents for whom \( \tilde{p}_{(i,j)}^k \) assigns probability one to a version who plays action \( A \), 70 agents for whom it assigns probability zero to such a version, and 1 agent for whom the probability is in \((0, 1)\). The cases (i), (ii), and (iii) below correspond to these three cases, respectively. The way we specify probabilities for case (iii) is clarified in (iii)-(a), (iii)-(b), and (iii)-(c).

\(^{15}\)Recall that each player \( j_i \) in \( Y(\Gamma, T) \) has the same number of information sets as player \( i \) in \( \Gamma \); here we abuse notation to use the same notation for an information set \( h \) in \( \Gamma \) and the information set in \( Y(\Gamma, T) \) of player \( j_i \) that includes the nodes corresponding to the nodes included in \( h \).
For all \((n,m) \in (\bigcup_{n' \in I} J_n) \setminus \{(i,j)\}\) and all \(l \in \{1, \ldots, |V_n|\}\), we set

(i) \(\tilde{p}^{k}_{(i,j)}(u^l_{(n,m)}) = 1\) if \(\sum_{l' \in \mathbb{N}, l' < l} \left[ T \cdot q^{k}_{i}(v^l_{n}) \right] < m \leq \sum_{l' \in \mathbb{N}, l' \leq l} \left[ T \cdot q^{k}_{i}(v^l_{n}) \right],\)

(ii) \(\tilde{p}^{k}_{(i,j)}(u^l_{(n,m)}) = 0\) if \(m \leq \sum_{l' \in \mathbb{N}, l' < l} \left[ T \cdot q^{k}_{i}(v^l_{n}) \right] \) or \(\sum_{l' \in \mathbb{N}, l' \leq |V_n|} \left[ T \cdot q^{k}_{i}(v^l_{n}) \right] < m \leq \sum_{l' \in \mathbb{N}, l' \leq |V_n|} \left[ T \cdot q^{k}_{i}(v^l_{n}) \right],\)

(iii) \(\tilde{p}^{k}_{(i,j)}(u^l_{(n,m)}) \in [0, 1]\) if \(\sum_{l' \in \mathbb{N}, l' \leq |V_n|} \left[ T \cdot q^{k}_{i}(v^l_{n}) \right] < m \leq T.\)

To define \(\tilde{p}^{k}_{(i,j)}\) for case (iii) concretely, for each \(n \in I\) and \(l' \in \{1, \ldots, |V_n|\}\), let

\[ f(l'; n, q^{k}_{i}) = T \cdot q^{k}_{i}(v^l_{n}) - \left[ T \cdot q^{k}_{i}(v^l_{n}) \right]. \]

That is, \(f(l'; n, q^{k}_{i})\) is the error that the approximation in (i) and (ii) above miss out. More specifically, (i) and (ii) assign too small a weight for each possible version in the support of the conjecture, and \(f(l'; n, q^{k}_{i})\) is the probability that needs to be added to make the conjecture exactly in line with the original conjecture \(q^{k}_{i}\). Now we allocate these probabilities to remaining agents considered in (iii). To do this, we define \(l(w; n, q^{k}_{i})\) for each \(w \in \mathbb{N}\) with \(w \leq \sum_{l' \in \mathbb{N}, l' \leq |V_n|} f(l'; n, q^{k}_{i})\) as follows:

\[ \sum_{l' \in \mathbb{N}, l' < (w; n, q^{k}_{i})} f(l'; n, q^{k}_{i}) < w \leq \sum_{l' \in \mathbb{N}, l' \leq (w; n, q^{k}_{i})} f(l'; n, q^{k}_{i}). \]

That is, \(l(w; n, q^{k}_{i})\) is the maximum number of versions such that the sum of the error probabilities can be no more than \(w\), when we add these errors in the order of the indices of the versions.
Then we define

(iii)-(a) \( \tilde{p}_{k(i,j)}(ul(i,j)) = \left( \sum_{l' \in N_1} f(l'; n, q^k_i) \right) - (w - 1) \)

if \( m = \sum_{l' \in N_1} T \cdot q^k_i(v^l_n) + w \text{ and } l = l(w - 1; n, q^k_i) \),

(iii)-(b) \( \tilde{p}_{k(i,j)}(ul(i,j)) = f(l; n, q^k_i) \)

if \( m = \sum_{l' \in N_1} T \cdot q^k_i(v^l_n) + w \text{ and } l(w - 1; n, q^k_i) < l < l(w; n, q^k_i) \),

(iii)-(c) \( \tilde{p}_{k(i,j)}(ul(i,j)) = w - \left( \sum_{l' \in N_1} f(l'; n, q^k_i) \right) \)

if \( m = \sum_{l' \in N_1} T \cdot q^k_i(v^l_n) + w \text{ and } l = l(w; n, q^k_i) \).

Note that \((i,j)\) has only \( T - 1 \) opponents in player role \( i \), so the above specification of the belief may not give rise to the conjecture that exactly corresponds to the one in the heterogenous model. However it will not lead to violation of best response condition, as beliefs about the strategy of agents of player \( i \) do not affect the expected payoff of an agent in player role \( i \).

Last, we construct a belief of \( u^k_{(i,j)} \), denoted \( \tilde{\mu}^k_{(i,j)} \), that is used to satisfy the best response condition. We let \( \tilde{\mu}^k_{(i,j)} \) to be defined by the following rule. First,

\[
\tilde{\mu}^k_{(i,j)}(\pi - (i,j)) = \sum_{\pi_{-1}(i,j) = \pi_{-1}(u_{-1}(i,j))} \tilde{p}^k_{(i,j)}(u_{-1}(i,j)).
\]

Second, \( (\tilde{\mu}^k_{(i,j)})_h \) is computed by Bayes rule under \( b_{(i,j)}(\tilde{\mu}^k_{(i,j)}) \) if \( h \in H(\hat{\pi}_{-1}) \) (note that Bayes rule induces a well-defined probability distribution at such \( h \) under \( b_{(i,j)} \) because \( T > \frac{1}{2^2} \)). For \( h \not\in H(\hat{\pi}_{-1}) \), we set

\[
(\tilde{\mu}^k_{(i,j)})_h (\hat{a}_i(h), (\hat{\pi}(n,m))_{(n,m) \in \cup_{w \neq i} J_w}) = 1
\]
where \( \hat{\pi}(n, m)(h') = \hat{\pi}_n(h') \) holds for all \( h' \in H_n \) for all \( n \in I \) and

\[
\hat{\pi}_n(h(x, ((i, j), (n, r_n)_{n \neq i}))) = \frac{1}{T|\Pi| - 1}\hat{a}_n(h)(x)
\]

for each \( (n, r_n)_{n \neq i} \in \times_{n \neq i} J_n \) and \( (x, ((i, j), (n, r_n)_{n \neq i})) \in h_n \).

b) Constructing the actual versions

We specify the actual versions \( u^* \) as follows: For each \( i \in I \) and each \((i, j)\), we set

\[
u^*_i = u^k_i \quad \text{if} \quad \sum_{k' \in \mathbb{N}, k' < k} \left[ T \cdot \phi_i(v_i^{k'}) \right] < m \leq \sum_{k' \in \mathbb{N}, k' \leq k} \left[ T \cdot \phi_i(v_i^{k'}) \right],
\]

\[
u^* = u^l_i \quad \text{if} \quad \sum_{k' \in \mathbb{N}, k' \leq |V_i|} \left[ T \cdot \phi_i(v_i^{k'}) \right] < m \leq T, \quad \phi_i(v_i^l) > 0 \quad \text{and} \quad \phi_i(v_i^{l'}) = 0 \quad \text{for all} \ l' < l.
\]

Let \( \pi^{**} = \pi(u^*) \).

c) Checking that the conditions of unitary \( \epsilon \)-RPCE hold

Since \( \frac{T - \sum_{k' \in \mathbb{N}, k' \leq |V_i|} \left[ T \cdot \phi_i(v_i^{k'}) \right]}{T} \leq \frac{|V_i|}{T} < \epsilon \), it is straightforward that \( \pi^{**} \) represents \( (\pi^{**}_{(i,1)}, \ldots, \pi^{**}_{(i,T)}) \) for each \( i \). Also, by definition \( \pi^{**} \) is generated by \( u^* \). Coherency holds for each \( i \in I \), each \((i, j)\) \in \( J_i \) and each \( k \in \{1, \ldots, |V_i|\} \) by the construction of \( \tilde{\mu}_i^{(i,j)} \). Accordance holds by construction. Moreover, the best response condition holds by construction (recall that randomization is conducted independently across players in the construction of \( \tilde{\mu}_i^{(i,j)} \)). Thus it remains to check the self-confirming condition and the observational consistency condition. To this end, we first note that, for any \( \Gamma \) and \( T \), \( D_{(i,j)} \) in the model \( Y(\Gamma, T) \) can be seen as an element in the same space as \( D_i \) in the model \( \Gamma \) by the construction of the terminal node partitions in \( Y(\Gamma, T) \). Henceforth, we abuse notation to write \( D_i = D_{(i,j)} \).

The self-confirming condition is satisfied in the original heterogeneous RPCE, so for each \( v_i^k \) in the support of \( \phi_i \), there exists \( \tilde{\pi}_{-i} \in \Pi_{-i} \) such that (i) \( (V, \phi) \)
induces $\tilde{\pi}_j$ for version $v^k_i$ for each $j \neq i$ and (ii) $D_i(\pi^k_i, \tilde{\pi}_{-i}) = D_i(\pi^*_i, \pi^*_i)$.

First, by the construction of $\tilde{\pi}^k_{(i,j)}$ and $\tilde{p}^k_{(i,j)}$ and Claim 2 that we present below (i) implies:

$$\|D_i(\tilde{\pi}^k_{(i,j)}, \pi_{-(i,j)}(u_{-(i,j)})) - D_i(\pi^k_i, \tilde{\pi}_{-i})\| \leq (\#A)^2 \|((\tilde{\pi}^k_{(i,j)}, \tilde{\pi}_{-i}) - (\pi^k_i, \pi_{-i}))\| \leq (\#A)^2 \frac{\max_{n \neq i} |V_n|}{T} < \frac{\epsilon}{2}$$

for each $u_{-(i,j)}$ in the support of $\tilde{p}^k_{(i,j)}$, where $\tilde{\pi}_n$ represents $(\pi^*_n(u_{-(i,j)}))(n,m)\in J_n$ for each $n \neq i$.

Second, by the construction of the actual versions $u^*$ and Claim 2, we have that

$$\|D_i(\pi^k_i, \pi^*_i) - D_i(\pi^k_i, \pi^*_i)\| \leq (\#A)^2 \|((\pi^k_i, \pi^*_i) - (\pi^k_i, \tilde{\pi}_{-i}))\| \leq (\#A)^2 \frac{\max_{n \neq i} |V_n|}{T} < \frac{\epsilon}{2},$$

where $\tilde{\pi}_n$ represents $(\pi^*_n(u_{-(i,j)}))(n,m)\in J_n$ for each $n \neq i$.

Thus, by the triangle inequality,

$$\|D_i(\pi^k_i, \pi_{-(i,j)}(u_{-(i,j)})) - D_i(\pi^k_i, \pi^*_i)\| \leq \epsilon$$

for each $u_{-(i,j)}$ in the support of $\tilde{p}^k_{(i,j)}$.

Thus, $v_i = (\pi_i, p_i)$ is $\epsilon$-self-confirming with respect to $\pi^*$.

The observational consistency condition is satisfied in the original heterogeneous RPCE, so for each $v^k_i$, $q^k_i(v^l_n) > 0$ implies that there exists $\tilde{\pi}_{-n} \in \Pi_{-n}$ such that (i’) $(V, \phi)$ induces $\tilde{\pi}_w$ for each $w \neq n$ and (ii’) there exists $\tilde{\pi}_{-n} \in \Pi_{-n}$ such that (ii’)-v) $(V, \phi)$ induces $\tilde{\pi}_w$ for version $v^l_n$ for each $w \neq n$ and (ii)-v) $D_n(\pi_n(v^l_n), \tilde{\pi}_{-n}) = D_n(\pi_n(v^l_n), \tilde{\pi}_{-n})$.

First, by the construction of $\tilde{\pi}^l_{(n,m)}$ and $\tilde{p}^l_{(n,m)}$ and Claim 2, we have that (ii’)-v) implies:

$$\|D_n(\pi_{(n,m)}(u^l_{(n,m)}), \pi_{-(n,m)}(u_{-(n,m)})) - D_n(\pi_{(n,m)}(v^l_n), \tilde{\pi}_{-n})\| \leq \epsilon$$
for each \( u_{-(n,m)} \) in the support of \( \bar{p}^l_{(n,m)} \), where \( \hat{\pi}_w \) represents \((\pi_{-(n,m)}(u_{-(n,m)}))_{(w,r) \in \tilde{J}_w} \) for each \( w \neq n \).

Second, by the construction of \( \bar{p}^k_{j_i} \) and Claim 2, we have that (i') implies:

\[
\|D_n(\pi_{(n,m)}(v^l_{n,m}), \hat{\pi}_{-n}) - D_n(\pi_{(n,m)}(u^l_{n,m}), (\pi(v_{i,j}), \tilde{v}_{-(i,j)}))_{-(n,m)}\| \leq \frac{\epsilon}{2}
\]

\[
(\#A)^2\|((\pi_{(n,m)}(u^l_{n,m})), \hat{\pi}_{-n}) - (\pi_{(n,m)}(v^l_{n,m}), \hat{\pi}_{-n})\| \leq \frac{\epsilon}{2}
\]

where \( \hat{\pi}_w \) represents \((\pi(u_{i,j}), \tilde{u}_{-(i,j)}))_{(w,r) \in \tilde{J}_w} \) for each \( w \neq n \).

Thus, by the triangle inequality, for all \( \tilde{u}_{(n,m)} \) in the support of \( \bar{p}^k_{(i,j)} \), it must be the case that for all \( u_{-(n,m)} \) in the support of the conjecture of \( \tilde{u}_{(n,m)} \),

\[
\|D_n(\pi_{(n,m)}(\tilde{u}_{(n,m)}), \pi_{-(n,m)}(u_{-(n,m)})) - D_n(\pi_{(n,m)}(\tilde{u}_{(n,m)}), (\pi(u_{i,j}), \tilde{u}_{-(i,j)}))_{-(n,m)}\| \leq \frac{\epsilon}{2} + 0 + \frac{\epsilon}{2} = \epsilon.
\]

Thus, \( u_{j_i} \) is \( \epsilon \)-observationally consistent. \( \blacksquare \)

Finally, we provide the statement and the proof of the claim in the above proof.

**Claim 2** For all \( \pi, \pi' \in \Pi \) and \( i \in I \), \( \|D_i(\pi) - D_i(\pi')\| \leq (\#A)^2 \cdot \|\pi - \pi'\| \) holds.

**Proof.** First we show that \( \|d(\pi) - d(\pi')\| \leq |A| \cdot \|\pi - \pi'\| \) for any \( \pi, \pi' \in \Pi \). To see this, fix \( \pi \) and \( \pi' \), and let \( \|\pi - \pi'\| = \epsilon \). Let \( A(z) \) be the set of actions that are taken to reach \( z \in Z \), \( h(a) \) be the information set such that action \( a \) can be taken, and \( j(a) \) be the player such that \( h(a) \in H_{j(a)} \). For any \( z \in Z \),
\[ |d(\pi)(z) - d(\pi')(z)| = \left| \prod_{a \in A(z)} \pi_{j(a)}(h(a))(a) - \prod_{a \in A(z)} \pi'_{j(a)}(h(a))(a) \right| \]

\leq \left| \prod_{a \in A(z)} \max\{\pi_{j(a)}(h(a))(a), \pi'_{j(a)}(h(a))(a)\} - \prod_{a \in A(z)} \min\{\pi_{j(a)}(h(a))(a), \pi'_{j(a)}(h(a))(a)\} \right| \]

\leq \left| \prod_{a \in A(z)} \max\{\pi_{j(a)}(h(a))(a), \pi'_{j(a)}(h(a))(a)\} - \prod_{a \in A(z)} (\max\{\pi_{j(a)}(h(a))(a), \pi'_{j(a)}(h(a))(a)\} - \varepsilon) \right| \]

\leq 1 - (1 - \varepsilon)^{|A|} \leq |A| \cdot \varepsilon = |A| \|\pi - \pi'||.

Hence,

\[ ||d(\pi) - d(\pi')|| \leq |A| \cdot ||\pi - \pi'||. \quad (1) \]

Next, for any \( i \in I \),

\[ ||D_i(\pi) - D_i(\pi')|| = \max_{P^i} |D_i(\pi)(P^i) - D_i(\pi')(P^i)| = \max_{P^i} \sum_{z \in P^i} (d(\pi)(z) - d(\pi')(z)) \]

\leq \max_{P^i} \sum_{z \in P^i} |d(\pi)(z) - d(\pi')(z)| \leq \sum_{z \in Z} |d(\pi)(z) - d(\pi')(z)| \]

\leq |Z| \cdot \max_{z \in Z} |d(\pi)(z) - d(\pi')(z)| \leq |A| \cdot ||d(\pi) - d(\pi')||. \quad (2) \]

Combining equations (1) and (2), we have that \( ||D_i(\pi) - D_i(\pi')|| \leq (|A|)^2 \cdot ||\pi - \pi'||. \]
