Dominant Currency Paradigm†

By Gita Gopinath, Emine Boz, Camila Casas, Federico J. Díez, Pierre-Olivier Gourinchas, and Mikkel Plagborg-Møller*

We propose a “dominant currency paradigm” with three key features: dominant currency pricing, pricing complementarities, and imported inputs in production. We test this paradigm using a new dataset of bilateral price and volume indices for more than 2,500 country pairs that covers 91 percent of world trade, as well as detailed firm-product-country data for Colombian exports and imports. In strong support of the paradigm we find that (i) noncommodities terms-of-trade are uncorrelated with exchange rates; (ii) the dollar exchange rate quantitatively dominates the bilateral exchange rate in price pass-through and trade elasticity regressions, and this effect is increasing in the share of imports invoiced in dollars; (iii) US import volumes are significantly less sensitive to bilateral exchange rates, compared to other countries’ imports; (iv) a 1 percent US dollar appreciation against all other currencies predicts a 0.6 percent decline within a year in the volume of total trade between countries in the rest of the world, controlling for the global business cycle. We characterize the transmission of, and spillovers from, monetary policy shocks in this environment. (JEL E52, F14, F31, F44)

Nominal exchange rates have always been at the center of fierce economic and political debates on spillovers, currency wars, and competitiveness. It is easy to understand why: in the presence of price rigidities, nominal exchange rate fluctuations are associated with fluctuations in relative prices and therefore have consequences for real variables such as the trade balance, consumption, and output.

The relationship between nominal exchange rate fluctuations and other nominal and real variables depends critically on the currency in which prices are rigid. The first generation of New Keynesian (NK) models, the leading paradigm in international macroeconomics, assumes prices are sticky in the currency of the producing country. Under this “producer currency pricing” paradigm (PCP), the law of one price holds and a nominal depreciation raises the price of imports relative to exports (the terms-of-trade) thus improving competitiveness. This paradigm was developed in the seminal contributions of Mundell (1963), Fleming (1962), Svensson and van Wijnbergen (1989), and Obstfeld and Rogoff (1995).

There is, however, pervasive evidence that the law of one price fails to hold. Out of this observation grew a second pricing paradigm. In the original works of Betts and Devereux (2000) and Devereux and Engel (2003), prices are instead assumed to be sticky in the currency of the destination market. Under this “local currency pricing” paradigm (LCP), a nominal depreciation lowers the price of imports relative to exports, a decline in the terms-of-trade, thus worsening competitiveness. Both paradigms have been extensively studied in the literature and are surveyed in Corsetti, Dedola, and Leduc (2010).

Recent empirical work on the currency of invoicing of international prices questions the validity of both approaches. Firstly, there is very little evidence that the best description of pricing in international markets follows either PCP or LCP. Instead, the vast majority of trade is invoiced in a small number of “dominant currencies,” with the US dollar playing an outsized role. This is documented in Goldberg and Tille (2008) and in Gopinath (2015). Secondly, exporters price in markets characterized by strategic complementarities in pricing that give rise to variations in desired markups. Thirdly, most exporting firms employ imported inputs in production, reducing the value-added content of exports. The workhorse NK models in the literature à la Galí and Monacelli (2005) instead assume constant demand elasticity and/or abstract from intermediate inputs.

Based on these observations, this paper proposes an alternative: the “dominant currency paradigm” (DCP). Under DCP, firms set export prices in a dominant currency (most often the dollar) and change them infrequently. They face strategic complementarities in pricing, and there is roundabout production using domestic and foreign inputs. We then test this paradigm using a newly constructed dataset of bilateral price and volume indices for more than 2,500 country pairs that covers 91 percent of world trade, and a firm-level database of the universe of Colombian exports and imports.

According to DCP, the following should hold true. First, at both short and medium horizons the terms-of-trade should be insensitive to exchange rate fluctuations. Second, for non-US countries, exchange rate pass-through into import prices (in home currency) should be high and driven by the dollar exchange rate as opposed to

---

1 Burstein and Gopinath (2014) surveys the evidence on variable markups.
2 The fact that most exporters are also importers is well documented. See Bernard, Jensen, and Schott (2009); Kugler and Verhooogen (2009); and Manova and Zhang (2009) among others. This is also reflected in the fact that value-added exports are significantly lower than gross exports, particularly for manufacturing, as documented in Johnson (2014) and Johnson and Noguera (2012). Amiti, Itskhoki, and Konings (2014) presents empirical evidence of the influence of strategic complementarities in pricing and of imported inputs on pricing decisions of Belgian firms.
the bilateral exchange rate. For the United States, on the contrary, pass-through into import prices should be low. Third, for non-US countries, import quantities should be driven by the dollar exchange rate as opposed to the bilateral exchange rate. In addition, US import quantities should be less responsive to dollar exchange rate movements as compared to non-US countries. Fourth, when the dollar appreciates uniformly against all other currencies, it should lead to a decline in trade between countries in the rest of the world (i.e., excluding the United States).

The stability of the terms-of-trade under DCP follows from the pricing of imports and exports in a common currency and the low sensitivity of these prices to exchange rate fluctuations. This contrasts with the predictions of the PCP and LCP paradigms. Under PCP (LCP) the terms-of-trade depreciates (appreciates) almost one-to-one with the exchange rate as the price of imports rises (is stable) alongside stable (rising) export prices, in home currency. It also differs from predictions of models with flexible prices and strategic complementarities in pricing such as Atkeson and Burstein (2008) and Itskhoki and Mukhin (2017). Unlike these models, the terms-of-trade stability under DCP is associated with volatile movements of the relative price of imported to domestic goods for nondominant (currency) countries. Furthermore, this volatility is driven by fluctuations in the value of the country’s currency relative to the dominant currency, regardless of the country of origin of the imported goods. Consequently, demand for imports depends on the value of a country’s currency relative to the dominant currency. When a country’s currency depreciates relative to the dominant currency, all else equal, it reduces its demand for imports from all countries.

In the case of exports, in contrast to PCP, which associates exchange rate depreciations with increases in quantities exported (controlling for demand), DCP predicts a negligible impact on goods exported to the dominant-currency destination. For exporting firms whose dominant currency prices are unchanged, there is no increase in exports. For those firms changing prices the rise in marginal cost following the rise in the price of imported inputs and the complementarities in pricing dampen their incentive to reduce prices, leaving exports mostly unchanged. The impact on exports to nondominant currency destinations depends on the fluctuations of the exchange rate of the destination country currency with the dominant currency. If the exchange rate is stable then DCP predicts a weak impact on exports to non-dollar destinations. On the other hand, if the destination country currency weakens (strengthens) relative to the dominant currency it can lead to a decline (increase) in exports.

Fluctuations in the value of dominant currencies can also have implications for cyclical fluctuations in global trade (the sum of exports and imports). Under DCP, a strengthening of dominant currencies relative to non-dominant ones is associated with a decline in imports across the periphery without a significant increase in exports to dominant currency markets, thus negatively impacting global trade. In contrast, in the case of PCP, the rise in competitiveness for the periphery generates an increase in exports. Moreover, the increase in exports dampens the decline in imports as production relies on imported intermediate inputs. In the case of LCP, both the import and export response is muted so the impact on global trade is weak.

We further demonstrate numerically that the different paradigms lead to contrasting implications for the transmission of monetary policy shocks within and across countries. With a Taylor rule, the inflation-output trade-off in response to a monetary
policy (MP) shock for a nondominant currency worsens under DCP relative to PCP. That is, a monetary policy rate cut raises inflation by much more than it increases output, as compared to PCP. Further, under DCP, contractionary MP shocks in the dominant country have strong spillovers to MP in the rest of the world and reduce rest-of-world and global trade, while MP shocks in nondominant currency countries generate only weak spillovers and have little impact on world trade.

Our empirical findings strongly support the predictions of DCP. Using the global database of bilateral trade price and volume indices we show the following. First, a regression of the bilateral noncommodities terms-of-trade on changes in the bilateral exchange rate yields a contemporaneous coefficient on the exchange rate of 0.037, with a 95 percent confidence interval [0.02, 0.05], consistent with DCP. For comparison, the coefficient should be close to 1 under PCP and to −1 under LCP.

For our second finding, we estimate exchange rate pass-through and trade elasticity regressions at the country-pair level. We first follow standard practice and estimate the pass-through of bilateral exchange rates into import prices and volumes. We document that when country j’s currency depreciates relative to country i by 10 percent, import prices in country j for goods imported from country i rise by 8 percent, suggestive of close to complete pass-through at the one-year horizon. However, adding the US dollar exchange rate as an additional explanatory variable and controlling for the global business cycle with time fixed effects knocks the coefficient on the bilateral exchange rate from 0.76 down to 0.16. The coefficient on the dollar exchange rate of 0.78 largely dominates that of the bilateral exchange rate. Moreover, the magnitude of the dollar pass-through is systematically related to the dollar invoicing shares of countries. Specifically, increasing the dollar invoicing share by 10 percentage points causes the contemporaneous dollar pass-through to increase by 3.5 percentage points. Similar to the price regressions, adding the US dollar exchange rate to a bilateral volume forecasting regression knocks down the coefficient on the bilateral exchange rate by a substantial amount. The contemporaneous volume elasticity for the dollar exchange rate is −0.19, while the elasticity for the bilateral exchange rate is an order of magnitude smaller at −0.03.

These pass-through estimates point to a potential misspecification in the standard pass-through regressions that ignore the role of the dollar. We also show that the dollar’s role as an invoicing currency is indeed special, as it handily beats the explanatory power of the euro in price and volume regressions. The data are also consistent with an additional key prediction of the dominant currency paradigm: US import prices and volumes are significantly less sensitive to the exchange rate, as compared to other countries’ imports.

Third, we demonstrate empirically that the strength of the US dollar is a key predictor of rest-of-world (i.e., excluding the United States) trade volume and inflation, again controlling for measures of the global business cycle. We find that a 1 percent appreciation of the US dollar relative to all other currencies is associated with a 0.6 percent contraction in rest-of-world aggregate import volume within the year.

---

3 This follows naturally from the classic Mundell-Fleming paradigm, according to which the price an importing country faces (when expressed in the importing country’s currency) fluctuates closely with the bilateral exchange rate. Accordingly, studies of exchange rate pass-through focus on trade-weighted or bilateral exchange rate changes (Goldberg and Knetter 1997, Burstein and Gopinath 2014).
Furthermore, countries with larger dollar import invoicing shares experience higher pass-through of the dollar exchange rate into consumer and producer price inflation.

The global database has the advantage of covering almost all of world trade, but it is not at the firm level and is only available at an annual frequency. We demonstrate that all our aggregate findings hold also when we use firm-level data from Colombia, a small open economy that is representative of emerging markets in its heavy reliance on dollar invoicing with 98 percent of exports invoiced in dollars. Using prices and quantities defined at the firm-10-digit product-country (origin or destination) quarter (or year) level for manufactured goods (excluding petrochemical and basic metal industries), we confirm that the US dollar exchange rate knocks down the bilateral exchange rate for price pass-through and trade elasticity of exports and imports to/from non-dollarized economies. Further, we demonstrate that DCP is able to match the dynamics of price pass-through.

To further contrast the different pricing paradigms, we simulate a model economy that is subject to commodity price shocks, productivity shocks, and third country exchange rate shocks, all calibrated to Colombia, and test its ability to match the data. Using a combination of calibration and estimation, we document that the data strongly reject PCP and LCP in favor of DCP. We demonstrate that all features of DCP matter for quantitatively matching the facts, including strategic complementarities in pricing and imported input use. Under our benchmark DCP specification we find, in line with the data, the export pass-through at four quarters to both dollar and non-dollar destinations to be 65 percent. Instead, when we shut down strategic complementarities and imported input use, the predicted pass-through declines by one-half to 30 percent.

Related Literature.—Our paper is related to a relatively small literature that models dollar pricing. These include Corsetti and Pesenti (2005); Goldberg and Tille (2008, 2009); Devereux, Shi, and Xu (2007); Cook and Devereux (2006); and Canzoneri et al. (2013). All of these models, with the exception of Canzoneri et al. (2013), are effectively static with one-period-ahead price stickiness. Unlike Canzoneri et al. (2013), we explore a three-region world, which is crucial to analyze differences between dominant and nondominant currencies. Goldberg and Tille (2009) explores three regions but in a static environment. In addition, the dollar pricing literature assumes constant desired markups and production functions that use only labor.

Our contribution to this literature is two-fold. Firstly, we develop a new Keynesian open economy model that combines dynamic dominant currency pricing, variable markups, and imported input use in production. We develop testable implications and demonstrate the differential transmission of monetary policy shocks across countries. Secondly, we empirically evaluate the dominant currency paradigm using two novel databases described previously.

Our empirical evidence on the terms-of-trade is related to Obstfeld and Rogoff (2000), which conducts one of the earliest tests of the Mundell-Fleming paradigm against the Betts-Devereux-Engel paradigm. Obstfeld and Rogoff (2000) examines the correlation between country-level terms-of-trade and the trade-weighted exchange rate for 21 countries, using quarterly data for 1982–1998. They report an average correlation of 0.26, which they interpret as a rejection of local currency
pricing. Even though the correlation is well less than 1, which would lend weak support for producer currency pricing, they conjecture that the low correlation could be because of the construction of the trade-weighted exchange rates and/or because their terms-of-trade measures include commodity prices. With the help of our globally representative dataset, we improve upon Obstfeld and Rogoff (2000) in several dimensions. Specifically, we examine the bilateral terms-of-trade, excluding commodity prices, and we estimate pass-through coefficients as opposed to correlations. Moreover, we test additional predictions of the different pricing paradigms.

Our exchange rate pass-through analysis is among the first to exploit a globally representative dataset on bilateral trade volumes and values. To our knowledge, the only other work that utilizes a similarly rich dataset is Bussière, Gaulier, and Steingress (2016), which analyzes trade prices and quantities at the product level.4

The remaining literature on exchange rate pass-through falls into two main camps. First, many papers use unilateral (i.e., country-level) time series, which limits the ability to analyze cross-sectional heterogeneity and necessitates the use of trade-weighted rather than truly bilateral exchange rates (e.g., Leigh et al. 2015). Second, a recent literature estimates pass-through of bilateral exchange rates into product-level prices, as opposed to unit values, but these micro datasets are available for only a few countries (see the review by Burstein and Gopinath 2014). The evidence on asymmetric responses of the volume of exports and imports is consistent with that documented by Alessandria, Pratap, and Yue (2013) for exports and Gopinath and Neiman (2014) for imports.5

Outline.—Section I presents the DCP model, proposes testable implications, and contrasts the transmission of monetary policy shocks across pricing paradigms. Section II empirically tests the implications derived in Section I using the global database. Section III tests and estimates the model using the Colombian microdata. Section IV concludes.

I. Model

Consider an economy $j$ that trades goods and assets with the rest of the world. The nominal bilateral exchange rate between country $j$ and another country $i$ is denoted $\mathcal{E}_{ij}$, expressed as the price of currency $i$ in terms of currency $j$. We assume that the US dollar is the dominant currency and let $\mathcal{E}_{sj}$ denote the price of a US dollar in currency $j$. An increase in $\mathcal{E}_{ij}$ (respectively, $\mathcal{E}_{sj}$) represents a depreciation of country $j$’s currency against that of country $i$ (respectively, the dollar).

As in the canonical open economy framework of Galí (2008), firms adjust prices infrequently à la Calvo. However, we depart from Galí (2008) along four dimensions. First, we nest three different pricing paradigms: producer currency pricing, local currency pricing, as well as dominant currency pricing. Second, the production

4 The goal of that paper is to quantify the elasticity of prices and quantities to the bilateral exchange rate and check if Marshall-Lerner conditions hold. In contrast, our goal is to empirically evaluate the predictions of the various pricing paradigms and in the process highlight the dollar’s central role in global trade.

5 The typical explanations for the sluggish export response relies on quantity frictions arising from sunk or search costs under PCP. DCP, consistent with the data, predicts that such relative prices are stable and therefore, does not require quantity frictions in the short term to generate slow adjustments in exports.
function uses not just labor but also intermediate inputs produced domestically and abroad. Third, we allow for strategic complementarity in pricing that gives rise to variable, as opposed to constant, markups. Last, international asset markets are incomplete with only riskless bonds being traded, while Galí (2008) assumes complete markets. We describe the details below.

A. Households

Country \( j \) is populated with a continuum of symmetric households of measure 1. In each period household \( h \) consumes a bundle of traded goods \( C_{j,t}(h) \). Each household also sets a wage rate \( W_{j,t}(h) \) and supplies an individual variety of labor \( N_{j,t}(h) \) in order to satisfy demand at this wage rate. Households own all domestic firms. To simplify exposition we omit the indexation of households when possible. The per-period utility function is separable in consumption and labor and given by

\[
U(C_{j,t}, N_{j,t}) = \frac{1}{1 - \sigma_c} C_{j,t}^{1 - \sigma_c} - \frac{\kappa}{1 + \varphi} N_{j,t}^{1 + \varphi}
\]

where \( \sigma_c > 0 \) is the household’s coefficient of relative risk aversion, \( \varphi > 0 \) is the inverse of the Frisch elasticity of labor supply and \( \kappa \) scales the disutility of labor.

The consumption aggregator \( C_{j,t} \) is implicitly defined by a Kimball (1995) homothetic demand aggregator,

\[
\sum_i \frac{1}{|\Omega_i|} \int_{\omega \in \Omega} \gamma_i \Upsilon\left(\frac{|\Omega_i|}{\gamma_i} C_{i,j,t}(\omega)\right) d\omega = 1.
\]

In equation (2), \( C_{i,j,t}(\omega) \) represents the consumption by households in country \( j \) of variety \( \omega \) produced by country \( i \) at time \( t \). The term \( \gamma_i \) is a set of preference weights that captures home consumption bias in country \( j \), with \( \sum_i \gamma_{ij} = 1 \), while \( |\Omega_i| \) is the measure of varieties produced in country \( i \). The function \( \Upsilon(\cdot) \) satisfies the constraints \( \Upsilon(1) = 1 \), \( \Upsilon'(\cdot) > 0 \), and \( \Upsilon''(\cdot) < 0 \). As is well known, this demand structure gives rise to strategic complementarities in pricing and variable markups. It captures the classic Dornbusch (1987) and Krugman (1987) channel of variable markups and pricing-to-market as described below.

Households in country \( j \) solve the following dynamic optimization problem,

\[
\max_{C_{j,t}, W_{j,t}, B_{j,t+1}} \sum_{t=0}^{\infty} \beta^t E_t \left[ U(C_{j,t}, N_{j,t}) \right],
\]

where \( E_t \) denotes expectations conditional on information available at time \( t \), subject to the per-period budget constraint expressed in home currency,

\[
P_{j,t} C_{j,t} + \mathcal{E}_{S_{j,t}}(1 + \beta_{j,t-1}^s) B_{j,t}^s + B_{j,t}
\]

\[
= W_{j,t}(h) N_{j,t}(h) + \Pi_{j,t} + \mathcal{E}_{S_{j,t}} B_{j,t+1}^s + \sum_{s' \in S} Q_{j,t}(s') B_{j,t+1}(s').
\]

In this expression, \( P_{j,t} \) is the price index for the domestic consumption aggregator \( C_{j,t} \). The term \( \Pi_{j,t} \) represents domestic profits transferred to domestic households,
owners of domestic firms. On the financial side, households trade a risk-free international bond denominated in dollars that pays a nominal interest rate $i^j_{t,t+1}$. The term $B^j_{t,t+1}$ denotes the dollar debt holdings of this bond at time $t$. They also have access to a full set of domestic state contingent securities (in $j$ currency) that are traded domestically and in zero net supply. Denoting $S$ the set of possible states of the world, $Q^j_{t,s}(s)$ is the period-$t$ price of the security that pays one unit of home currency in period $t + 1$ and state $s \in S$, and $B^j_{t,t+1}(s)$ are the corresponding holdings.

The optimality conditions of the household’s problem yield the following demand system:

\[
C_{ij,t}(\omega) = \gamma_{ij} \psi \left( \frac{D_{ij,t} P_{ij,t}(\omega)}{P_{ij,t}} \right) C_{j,t},
\]

where $\psi(\cdot) := \mathcal{T}^{-1}(\cdot) > 0$ so that $\psi(\cdot) < 0$, $D_{ij,t} := \sum_t \int_t \gamma^t(\omega) \left( \frac{[\Omega] C_{ij,t}(\omega)}{\gamma_{ij} C_{ij,t}} \right) \times \frac{C_{ip,t}(\omega)}{C_{ip,t}} d\omega$ is a demand index and $P_{ij,t}(\omega)$ denotes the price of variety $\omega$ produced in country $i$ and sold in country $j$, in currency $j$. Define the elasticity of demand $\sigma_{ij,t}(\omega) := -\partial \log C_{ij,t}(\omega)/\partial \log Z_{ij,t}(\omega)$, where $Z_{ij,t}(\omega) := D_{ij,t}(P_{ij,t}(\omega)/P_{ij,t})$. The log of the optimal flexible price markup is $\mu_{ij,t}(\omega) := \log (\sigma_{ij,t}/(\sigma_{ij,t} - 1))$. It is time-varying and we let $\Gamma_{ij,t}(\omega) := \partial \mu_{ij,t}/\partial \log Z_{ij,t}(\omega)$ denote the elasticity of that markup. By definition, the price index $P_{jt}$ satisfies $P_{jt} C_{jt} = \sum_i \int_t \Omega_t P_{ij,t}(\omega) C_{ij,t}(\omega) d\omega$.

Intertemporal optimality conditions for international and domestic bonds are given by the usual Euler equations:

\[
C_{j,t}^{-\sigma_{c}} = \beta (1 + i^j_{j,t}) E_t \left[ C_{j,t+1}^{-\sigma_{c}} \frac{P_{j,t}}{P_{j,t+1}} \frac{E_{s,t+1}^{s,t} S_{j,t}}{E_{s,t}^{s,t}} \right],
\]

\[
C_{j,t}^{-\sigma_{c}} = \beta (1 + i^j_{j,t}) E_t \left[ C_{j,t+1}^{-\sigma_{c}} \frac{P_{j,t}}{P_{j,t+1}} \right],
\]

where $(1 + i^j_{j,t}) = \left( \sum_{s \in S} Q^j_{t,s}(s)^{-1} \right)$ is the inverse of the price of a nominally risk-free $j$-currency bond at time $t$ that delivers one unit of $j$ currency in every state of the world in period $t + 1$.

Households are subject to a Calvo friction when setting wages in $j$-currency: in any given period, they may adjust their wage with probability $1 - \delta_w$, and maintain the previous-period nominal wage otherwise. As we will see, they face a downward sloping demand for the specific variety of labor they supply given by $N_{j,t}(h) = (W_{j,t}(h)/W_{j,t})^{\vartheta} N_{j,t}$, where $\vartheta > 1$ is the elasticity of labor demand and $W_{j,t}$ is the aggregate nominal wage in country $j$, defined below. The standard optimality condition for wage setting is given by

\[
\text{E}_{t} \sum_{s=t}^{\infty} \delta_{w}^{s-t} \Theta_{j,s} N_{j,s} W_{j,s}^{\vartheta(1+\varphi)} \left[ \frac{\vartheta}{\vartheta - 1} P_{j,s} C_{j,s}^{\sigma_{c}} N_{j,s}^{\sigma_{c}} - \frac{\bar{W}_{j,t}(h)^{1+\varphi}}{W_{j,s}^{\vartheta\varphi}} \right] = 0,
\]

where $\Theta_{j,s} := \beta^{s-t} (C_{j,s}^{-\sigma_{c}}/C_{j,t}^{-\sigma_{c}})(P_{j,s}/P_{j,t})$ is the stochastic discount factor between periods $t$ and $s \geq t$ used to discount profits and $\bar{W}_{j,t}(h)$ is the optimal nominal reset

---

{6} This dollar interest rate can be country-specific, hence the dependency on $j$ to reflect country risk premia, financial frictions, or to ensure stationarity of the linearized model.
wage in period $t$ and country $j$. This implies that $W_{j,t}(h)$ is preset as a constant markup over the expected weighted-average of future marginal rates of substitution between labor and consumption and aggregate wage rates, during the duration of the wage. Sticky wages are useful to match the empirical fact that wage-based real exchange rates move closely with the nominal exchange rates.

B. Producers

Each producer in $j$ manufactures a unique variety $\omega$, which is sold both domestically and internationally. The output of the firm is used both for final consumption and as an intermediate input for production. The production function uses a combination of labor $L_{j,t}$ and intermediate inputs $X_{j,t}$, with a Cobb-Douglas production function:

$$Y_{j,t} = \alpha L_{j,t}^{1-\alpha} X_{j,t}^{\alpha}$$

where $\alpha$ is the share of intermediates in production and $a_{j,t}$ is an aggregate productivity shock. The intermediate input aggregator $X_{j,t}$ takes the same form as the consumption aggregator in equation (2):

$$\sum_{i} \frac{1}{|\Omega_i|} \int_{\omega \in \Omega_i} \gamma_{ij} Y(\frac{|\Omega_i| X_{ij,t}(\omega)}{\gamma_{ij} X_{j,t}}) d\omega = 1,$$

where $X_{ij,t}(\omega)$ represents the demand by firms in country $j$ for variety $\omega$ produced in country $i$ as intermediate input. The labor input $L_{j,t}$ is a constant elasticity aggregator of the individual varieties $L_{j,t}(h)$ supplied by each household, $L_{j,t} = \left[ \int_{0}^{1} L_{j,t}(h) \left( \frac{\varphi - 1}{\varphi} \right) dh \right]^{\varphi/(\varphi - 1)}$, with $\varphi > 1$.

By symmetry, a good produced in $j$ can be used for consumption or as an intermediate input in each country $i$ and the demand for domestic individual varieties (both for consumption and as intermediate input) takes a form similar to that in equation (5).

Markets are assumed to be segmented so firms can set different prices by destination market and invoicing currency. Denote $P_{j,i,t}(\omega)$ the price of a variety $\omega$ originating in $j$, sold in country $i$, and invoiced in currency $k$. The per-period nominal profits of the domestic firm producing variety $\omega$ are then given by

$$\Pi_{j,i,t}(\omega) = \sum_{i,k} \mathcal{E}_{ij,t} P_{j,i,t}(\omega) Y_{j,i,t}(\omega) - \mathcal{MC}_{j,t} Y_{j,t}(\omega),$$

with the convention that $\mathcal{E}_{j,i,t} := 1$. In that expression, $Y_{j,i,t}(\omega) = C_{j,i,t}(\omega) + X_{j,i,t}(\omega)$ is the demand for domestic variety $\omega$ from country $j$ invoiced in currency $k$ in country $i$, both for consumption and as an input in production, while $Y_{j,t}(\omega) = \sum_{i,k} Y_{j,i,t}(\omega)$ is the total demand across destination markets $i$ and invoicing currencies $k$. The term $\mathcal{MC}_{j,t}$ denotes the nominal marginal cost of country $j$ firms in their home currency. Given equation (9), it is given by

$$\mathcal{MC}_{j,t} = \frac{1}{\alpha \left( 1 - \alpha \right)} \cdot \frac{W_{j,t}^{1-\alpha} \mathcal{P}_{j,t}^{\alpha}}{e^{a_{j,t}}}.$$
The optimality conditions for hiring labor are given by

\[(1 - \alpha) \frac{Y_{jt}}{L_{jt}} = \frac{W_{jt}}{MC_{jt}}, \quad L_{jt}(h) = \left(\frac{W_{jt}(h)}{W_{jt}}\right)^{-\delta} L_{jt},\]

with the aggregate nominal wage \(W_{jt}\) defined as \(W_{jt} = \left[\int W_{jt}(h)^{1-\delta} dh\right]^{\frac{1}{1-\delta}}\), while the demand for intermediate inputs is determined by

\[\alpha \frac{Y_{jt}}{X_{jt}} = \frac{P_{jt}}{MC_{jt}}, \quad X_{jt}(\omega) = \gamma_{ij} \psi \left(D_{jt} \frac{P_{ji}(\omega)}{P_{jt}}\right) X_{jt} .\]

C. Pricing

Firms choose prices at which to sell in \(j\) and in international markets \(i\), with prices reset infrequently. As in Galí (2008), we consider a Calvo pricing environment where firms are randomly allowed to reset prices with probability \(1 - \delta_p\). A core focus of this paper is on the implications of various pricing choices by firms, in particular under dominant currency pricing. Consequently, we assume that firms can set their prices either in the producer currency \((j)\), in the destination currency \((i)\), or in the dominant currency \$(S)\).

Denote \(\theta^k_{ji}\) the fraction of exports from region \(j\) to region \(i\) that are priced in currency \(k\), with \(\sum_k \theta^k_{ji} = 1\) for any pair \(\{i, j\}\). We allow for all pricing combinations but will focus on subsets. The benchmark of PCP corresponds to the case where \(\theta^k_{ji} = 1\) for every \(i \neq j\). The case of LCP corresponds to \(\theta^k_{ji} = 1\) for every \(i \neq j\). Under DCP, \(\theta^S_{ji} = 1\) for every \(i \neq j\). Lastly, we assume that all domestic prices are sticky in the home currency, an assumption consistent with a large body of evidence: \(\theta^j_{ji} = 1\) for every \(j\).

Consider the pricing problem of a firm from country \(j\) selling in country \(i\) and invoicing in currency \(k\), and denote \(\bar{P}^k_{ji,t}(\omega)\) its reset price. This reset price satisfies the following optimality condition:

\[E_t \sum_{s=t}^{\infty} \delta_p^{s-t} \Theta_{j,i,s} Y^k_{ji,s}(\omega) \left(\sigma^k_{ji,s}(\omega) - 1\right) \left(\varepsilon_{k,s} \bar{P}^k_{ji,s}(\omega) - \frac{\sigma^k_{ji,s}(\omega)}{\sigma^k_{ji,s}(\omega) - 1} MC_{j,s}\right) = 0.\]

In this expression, \(Y^k_{ji,s}(\omega)\) is the quantity sold in country \(i\) invoiced in currency \(k\) at time \(s\) by a firm that resets prices at time \(t \leq s\) and \(\sigma^k_{ji,s}(\omega)\) is the elasticity of demand. This expression implies that \(\bar{P}^k_{ji,t}(\omega)\) is preset as a markup over expected future marginal costs expressed in currency \(k\), \(MC_{j,s}(\omega)/\varepsilon_{k,s}\), over the duration of the price spell. Observe that because of strategic complementarities, the markup over expected future marginal costs is not constant.

D. Testable Implications

Before we close the model, we can already outline a number of testable implications of our framework for the joint behavior of exchange rates, export and import prices, and quantities. We explore them empirically in Section II.
Using lower cases to denote the log of variables (e.g., \( p_{ij} = \ln P_{ij} \)), country \( j \)'s import price inflation for goods originating from country \( i \) can be expressed as

\[
\Delta p_{ij,t} = \sum_k \theta^k_{ij} (\Delta p^k_{ij,t} + \Delta e^k_{ij,t}),
\]

where the summation is over invoicing currencies. Under Calvo pricing, \( \Delta p^k_{ij,t} = (1 - \delta_p) (p^k_{ij,t} - p^k_{ij,t-1}) \), and \( p^k_{ij,t} \) is the (log) reset-price defined in equation (15). If all goods from \( i \) to \( j \) are either producer-priced (PCP), locally-priced (LCP) or priced in the dominant currency (DCP), \( \theta^l_{ij} + \theta^s_{ij} + \theta^e_{ij} = 1 \) and we obtain

\[
(16) \quad \Delta p_{ij,t} = \theta^l_{ij} \Delta e_{ij,t} + \theta^s_{ij} \Delta e^s_{ji,t} + (1 - \delta_p) \sum_k \theta^k_{ij} (\bar{p}^k_{ij,t} - p^k_{ij,t-1}).
\]

In the very short run, \( \delta_p \rightarrow 1 \), and we can ignore the last term of the previous equation: changes in bilateral import prices and in the bilateral terms-of-trade \( TOT_{ij} = P_{ij} / (P^e_{ij} E^e_{ij}) \) only depend on the bilateral nominal exchange rates, the dollar exchange rate, and the share of trade invoiced in different currencies.

On the quantity side a log-linear approximation (around a symmetric steady state) of equations (5) and (14) yields

\[
\Delta y_{ij,t} = -\sigma_{ij} (\Delta p_{ij,t} - \Delta p_{ji,t}) + \Delta y^d_{ij,t},
\]

where \( \sigma_{ij} \) is the elasticity of demand and \( y^d_{ij,t} \) is the (log) of aggregate demand in country \( j \).

**PROPOSITION 1** (Pass-Through): When prices are fully rigid and predetermined in their currency of invoicing (\( \delta_p \rightarrow 1 \)), pass-through into bilateral import prices expressed in currency \( j \) and quantities from country \( i \) to country \( j \) (controlling for destination prices \( p_{ji,t} \) and demand \( y^d_{ji,t} \)) are given by

\[
(17) \quad \Delta p_{ij,t} = \theta^l_{ij} \Delta e_{ij,t} + \theta^s_{ij} \Delta e^s_{ji,t},
\]

\[
(18) \quad \Delta y_{ij,t} = -\sigma_{ij} (\theta^l_{ij} \Delta e_{ij,t} + \theta^s_{ij} \Delta e^s_{ji,t}).
\]

- **In the case of PCP**, \( \theta^l_{ij} = \theta^s_{ji} = 1 \) and

\[
\Delta p_{ij,t} = \Delta e_{ij,t}, \quad \Delta p_{ji,t} = -\Delta e_{ij,t},
\]

\[
\Delta tot_{ij,t} = \Delta p_{ij,t} - (\Delta p_{ji,t} + \Delta e_{ij,t}) = \Delta e_{ij,t},
\]

\[
\Delta y_{ij,t} = -\sigma_{ij} \Delta e_{ij,t}.
\]

- **In the case of LCP**, \( \theta^l_{ij} = \theta^s_{ji} = 1 \) and

\[
\Delta p_{ij,t} = 0, \quad \Delta p_{ji,t} = 0,
\]

\[
\Delta tot_{ij,t} = \Delta p_{ij,t} - (\Delta p_{ji,t} + \Delta e_{ij,t}) = -\Delta e_{ij,t},
\]

\[
\Delta y_{ij,t} = 0.
\]
• In the case of DCP, $\theta^S_{ij} = \theta^S_{ji} = 1$ and

$$\Delta p_{ij,t} = \Delta e_{sj,t}, \quad \Delta p_{ji,t} = \Delta e_{si,t},$$

$$\Delta tot_{ij,t} = \Delta p_{ij,t} - (\Delta p_{ji,t} + \Delta e_{ij,t}) = 0,$$

$$\Delta y_{ij,t} = -\sigma_{ij,t} \Delta e_{sj,t}.$$ 

It should be clear that the predictions for prices, when prices are yet to change, do not depend on what drives the exchange rate variation, that is, whether it arises from monetary policy shocks, financial shocks, or other shocks. Empirically, we should expect those countries relying more heavily on dollar pricing to display greater sensitivity to the dollar exchange rate, even when controlling for the bilateral exchange rate between countries $i$ and $j$. We summarize the testable implications of DCP below.

**Testable Implications** (Import Price and Quantity Pass-Through):

(i) **The bilateral terms-of-trade should be insensitive to bilateral exchange rates.**

(ii) **For non-US countries exchange rate pass-through into import prices (in home currency) should be high and driven by the dollar exchange rate as opposed to the bilateral exchange rate. Countries that rely more heavily on dollar import invoicing should see more of this effect. For the United States, on the contrary, pass-through into import prices should be low.**

(iii) **For non-US countries, import quantities should be driven by the dollar exchange rate as opposed to the bilateral exchange rate. US import quantities should be less responsive to dollar exchange rate movements as compared to non-US countries.**

(iv) **When all countries’ currencies uniformly depreciate relative to the dollar, it should lead to a decline in trade between the rest of the world (i.e., excluding the United States).**

The first three implications follow directly from Proposition 1. The last implication is obtained from the aggregation of import volumes across country-pairs where the United States is neither the origin nor the destination country. Denote $\mathbb{R}$ the set of such country-pairs: $\mathbb{R} \equiv \{(i,j), i \neq j, i \neq $, $j \neq $$\}$. Let $\omega_{ij}$ denote country $j$ total noncommodity import value from country $i$ in some reference year, normalized so that $\sum_{\mathbb{R}} \omega_{ij} = 1$. We conceptualize the rest-of-world aggregate trade bundle, $y_{\mathbb{R},t}$, as a Cobb-Douglas aggregate of individual-country bilateral (log) gross imports with weights $\omega_{ij}$: $y_{\mathbb{R},t} := \sum_{\mathbb{R}} \omega_{ij} y_{ij,t}$, *Ceteris paribus*, under DCP, a uniform
depreciation relative to the dollar $\Delta e_{S,t} > 0$, leads to a decline in noncommodity trade in the rest of the world:

$$\Delta y_{R,t} = \sum_{R} \omega_{ij} \Delta y_{ij,t} = - \left( \sum_{R} \omega_{ij} \sigma_{ij,t} \right) \Delta e_{S,t} < 0.$$  

Under either PCP or LCP, the growth of the rest-of-world trade is instead $\Delta y_{R,t} = 0$, either because bilateral non-dollar exchange rates are unchanged (under PCP) or because there is no bilateral pass-through (LCP).

As the horizon increases, the frequency of price adjustment increases and the pass-through predictions depend also on the response of reset prices $p_{ij,t}^k$ to exchange rates. We demonstrate in Section IIIB that the divergent predictions across the different paradigms hold at longer than annual frequencies in the presence of strategic complementarities in pricing and imported input use.8

E. Closing the Model and Contrasting Shock Transmission

Before turning to our empirical results, this subsection demonstrates the differential transmission of monetary policy (MP) shocks across different pricing paradigms in a Small Open Economy (SOE). Then, using a 3-country Large Open Economy (LOE) framework, it further documents the asymmetry in monetary policy spill-overs under DCP, depending on whether the MP shocks originate in the dominant currency country or elsewhere. We show that when countries follow a Taylor rule: (i) the inflation-output trade-off in response to a monetary policy shock for a small open economy worsens under DCP relative to PCP; (ii) MP shocks in the dominant country have strong spillovers to MP in the rest of the world and reduce rest-of-world and global trade, while MP shocks in nondominant currency countries generate only weak spillovers and little impact on world trade. Details of the simulations are provided in the online Appendix.

Closing the Model.—To evaluate shock transmission, we need to close the model. This requires that in addition to the equilibrium conditions specified in Section I we spell out the processes for interest rates and impose market clearing conditions. We assume that the nominal interest rate in each country $i$ is set by its monetary authority and follows a Taylor rule with inertia:

$$i_{i,t} - i^* = \rho_m(i_{i,t-1} - i^*) + (1 - \rho_m)(\phi_M \pi_{i,t} + \phi_Y \tilde{y}_{i,t}) + \varepsilon_{i,t}.$$  

8 This result does not depend on the exogeneity of the currency of invoicing. Some of the ingredients from our model, namely imported input use in production and strategic complementarities in pricing, are precisely those that would give rise endogenously to dominant currency in pricing. This is demonstrated by Gopinath, Itskhoki, and Rigobon (2010) in a partial equilibrium environment and Mukhin (2018) in a general equilibrium environment. Nonetheless, our testable predictions continue to hold, even after endogenizing the currency choice: as shown in Gopinath, Itskhoki, and Rigobon (2010), firms choose to price in currencies in which their reset prices are most stable, i.e., desired medium-run pass-through into the price (expressed in the invoicing currency) is low. In other words, our empirical findings will continue to be relevant in an environment with endogenous currency choice. Lastly, as the horizon increases the impact of exchange rate fluctuations on prices and quantities depend on the source of the shock. The ideal test would be to examine the joint response of exchange rates, prices, and quantities to an exogenous shock such as a monetary policy shock. The problem is that, in the data, exchange rate fluctuations have little to do with monetary policy shocks or other identified policy shocks. Instead exchange rates appear to be driven by a “residual” that the literature names “financial shocks.” Practically, this shows up as low power in testing the channel from identified exogenous shocks to exchange rates and to trade.
In this expression, $\phi_M$ captures the sensitivity of policy rates to consumer price inflation $\pi_{i,t} = \Delta \ln P_{i,t}$, $\phi_Y$ measures the sensitivity to the output gap $\tilde{y}_{i,t}$, $\rho_m$ captures the inertia in setting policy rates, while the target nominal interest rate is assumed equal to the steady state international borrowing rate $i^*$. Here, $\varepsilon_{i,t}$ evolves according to an AR(1) process, $\varepsilon_{i,t} = \rho_\varepsilon \varepsilon_{i,t-1} + \sigma_{\varepsilon_i}^m$ where $\sigma_{\varepsilon_i}^m$ are serially independently distributed innovations.9

Goods, labor, and domestic bond market-clearing conditions require $Y_{i,t}(\omega) = \sum_j (C_{ij,t}(\omega) + X_{ij,t}(\omega))$, $N_{i,t} = L_{i,t}$, and $B_{i,t}(s') = 0$, $\forall s' \in S$. The remaining market clearing conditions depend on whether we consider a small open economy (SOE) or a large open economy (LOE) environment. In the SOE case, all foreign variables are taken as exogenous and not impacted by shocks in the SOE. In the LOE case, we impose the additional requirement that $\sum B_{i,t}^s = 0$.

**Calibration.**—

**Preference Aggregator:** We adopt the Klenow and Willis (2016) functional form for the demand function $\Upsilon(\cdot)$. This gives rise to the following demand for individual varieties:

$$Y_{ij,t}(\omega) \equiv C_{ij,t}(\omega) + X_{ij,t}(\omega) = \gamma_i \left(1 + \epsilon \ln \frac{1}{\sigma} - \epsilon \ln Z_{ij,t}(\omega)\right)^{\sigma/\epsilon} (C_{j,t} + X_{j,t}),$$

where $Z_{ij,t}(\omega) \equiv D_{j,t} \left(P_{ij,t}(\omega)/P_{j,t}\right)$ as previously defined and $\sigma$ and $\epsilon$ are two parameters that determine the elasticity of demand and its variability as follows:

$$\sigma_{ij,t}(\omega) = \left(1 + \epsilon \ln \frac{1}{\sigma} - \epsilon \ln Z_{ij,t}(\omega)\right),$$

$$\Gamma_{ij,t}(\omega) = \left(\frac{\sigma - 1 - \epsilon \ln \frac{1}{\sigma} + \epsilon \ln Z_{ij,t}(\omega)}{\epsilon}\right).$$

In a symmetric steady state $Z_{ij,t}(\omega) = (\sigma - 1)/\sigma$, the elasticity of demand is $\sigma$ while the elasticity of the markup is $\Gamma = \epsilon/(\sigma - 1)$. Strategic complementarities and variable markups arise when $\epsilon > 0$, while $\epsilon = 0$ corresponds to the constant elasticity case.

**Parameter Values:** Table 1 lists parameter values employed in the simulation. The time period is a quarter. Several parameters are set to values standard in the

---

9In Section IIIB we examine moments of the stationary distribution for a small open economy. As is well known, in the absence of further assumptions the SOE model just described when solved around a well-behaved steady state with $\beta(1 + i^*) = 1$ is nonstationary in that the level of real debt and therefore other real variables are permanently changed even in response to transitory shocks. To induce stationarity we follow Schmitt-Grohé and Uribe (2003) and assume the dollar interest rate in country $i$ is an increasing function of its external debt, $\tilde{b}_t^i = b_{t,3} + \psi \left(e^{B_{i,1,t}/P_S} - \tilde{b}_t^i - 1\right) + \epsilon_{\tilde{b}_t}^i$, where $\psi > 0$ measures the responsiveness of the dollar rate to the country’s real dollar debt holdings $B_{i,1,t}/P_S$ where $P_S$ is exogenous from the SOE perspective. The term $\tilde{b}_t^i$ is the exogenous steady-state real dollar debt holdings. This is a standard assumption in the small open economy literature to induce stationarity in a log-linearized environment. Because of the dependence on aggregate debt individual households do not internalize the effect of their borrowing choices on the interest rate. In this section we study the impulse response to a small one-time shock and consequently the model with or without the stationarity assumption delivers almost identical results, as also shown by Schmitt-Grohé and Uribe (2003).
literature (see, e.g., Galí 2008). Following Christiano, Eichenbaum, and Rebelo (2011) we set the wage stickiness parameter $\delta_w = 0.85$ corresponding roughly to a year-and-a-half average duration of wages. The steady-state elasticity of substitution between varieties $\sigma$ is assumed in the model to be the same across and within regions. Accordingly, we calibrate to an average of these elasticities measured in the literature. Specifically, Broda and Weinstein (2006) obtains a median elasticity estimate of 2.9 for substitution across imported varieties, while Feenstra, Obstfeld, and Russ (2010) estimates a value close to 1 for the elasticity of substitution across domestic and foreign varieties. Thus, we set $\sigma = 2$.

To parameterize $\epsilon$, which controls the strength of the strategic complementarities, we rely on estimates from the micro pass-through literature that converges on very similar values for $\Gamma$ despite the differences in data and methodology. Following Amiti, Itskhoki, and Konings (2014, 2019) and Gopinath and Itskhoki (2011) we set $\Gamma = 1$. Because in steady state $\Gamma = \epsilon/(\sigma - 1)$ this implies $\epsilon = 1$. The home bias share is set to 0.7. This implies steady-state spending on imported goods in the consumption bundle and intermediate input bundle equal to 30 percent.10

Small Open Economy.—In this section we contrast the impulse responses to a monetary policy shock in an SOE (labeled H) under different pricing regimes. Figure 1 plots the impulse response to a 25 basis point exogenous cut in domestic interest rates (panel A). In each panel, we contrast the response under three regimes: Dominant Currency Paradigm (DCP), Producer Currency Pricing (PCP), and Local Currency Pricing (LCP).

10For the SOE case we assume exogenous rest-of-world demand such that exports as a ratio of GDP is 45 percent. The specific value of this ratio is not essential to the results.
Exchange Rate and Inflation: Following the monetary shock, domestic interest rates decline but less than one-to-one as the exchange rate $\epsilon_{Sfh}$ depreciates by around 0.8 percent (panel C of Figure 1) raising inflationary pressures on the economy (panel B). This in turn dampens the fall in nominal interest rates via the monetary policy rule. As seen in panel B, the increase in inflation in the case of DCP and PCP far exceeds that of LCP since exchange rate movements have a smaller impact on the domestic prices of imported goods when import prices are sticky in local currency.

Terms-of-Trade: The exchange rate depreciation is associated with almost a one-to-one depreciation of the terms-of-trade in the case of PCP and a one-to-one appreciation in the case of LCP (panel D of Figure 1). In contrast, under DCP, the terms-of-trade depreciate negligibly and remain stable because both export and import prices are stable in the dominant currency.
Exports and Imports: With stable export and import prices in the dominant currency under DCP, the home currency price of exports and imports rises with the exchange rate depreciation as depicted in panels E and F of Figure 1. This in turn generates a significant decline in trade-weighted imports (0.43 percent), despite the expansionary effect of monetary policy, and only a modest increase in trade-weighted exports (0.1 percent) (panels G and H). This contrasts with the PCP benchmark that generates a large increase in exports and with the LCP benchmark that generates an increase in imports (from the demand expansion). The decline in imports in the case of PCP is lower than that under DCP because of export expansion under PCP and the use of imported inputs.

Output: As depicted in panel I of Figure 1, the expansionary impact on output is muted under DCP relative to PCP, with the lowest impact under LCP. Under DCP, there is an expenditure switching effect from imports toward domestic output that is absent under LCP, while DCP misses out on the expansionary impact on exports under PCP. Comparing panel B and panel I, the inflation-output trade-off in response to expansionary monetary policy worsens under DCP relative to both PCP and LCP (where output does not expand much, but inflation increases the least). In the case of DCP, inflation rises by 0.35 percent on impact and output by 0.56 percent, a ratio of 0.4. In the case of PCP, that ratio is almost halved to 0.2/0.8 = 0.25. The ratio is lowest for LCP at 0.07.

Large Open Economies.—For the LOE case we consider three economies, U, G, and R. These economies are symmetric, except for international pricing and bond markets in which the dollar (the currency of U) is dominant. Assuming 100 percent dollar pricing in international trade, we focus on the asymmetry in the transmission of monetary policy shocks that originate in U, relative to those in G/R.

Monetary Policy Shock in Dominant Currency Country: We first consider a positive 25 basis point shock to the nominal interest rate in U. The impulse responses to this monetary tightening are plotted in Figure 2. The outcomes in G and R are the same for all variables, including their exchange rates, both of which depreciate by 0.65 percent relative to the dollar on impact.

The rise in interest rates in U leads to a decline in output (−0.6 percent, panel E), an appreciation of the dollar (0.65 percent, panel C), and a fall in inflation (−0.02 percent, panel D). The decline in inflation is, however, negligible (in contrast to PCP) because dollar pricing generates a low pass-through of the dollar appreciation into the price of imported goods, as seen in panel G of Figure 2. On the other hand, the pass-through into export prices (in the destination currency) is high, as depicted in panel H, which in turn generates a significant decline in exports (panel I). Imports decline because of the decline in overall demand given MP tightening so overall, the

11 We simulate the model also for the case when there is a full set of Arrow-Debreu securities traded. The impulse responses, qualitatively and quantitatively, are very close. This is intuitive because under perfect foresight, the noncontingent bond is sufficient to complete the market, i.e., the equilibrium conditions of the cases with complete markets and incomplete markets with a bond are the same. When an unanticipated shock hits, only the initial period’s equilibrium conditions differ across the two cases.
trade balance to GDP deteriorates mildly. The terms-of-trade (panel F) are largely unchanged.

The monetary tightening in $U$ has a larger effect on inflation on impact in $G/R$ (0.2 percent, panel D) than in $U$ because the depreciation has high pass-through into import prices of the former countries. This in turn generates an endogenous increase in interest rates (0.15 percent, panel B) in $G/R$ via the Taylor rule, leading to a mild contraction in output ($-0.03$ percent, panel E). Despite the depreciation of the $G/R$ exchange rates relative to the dollar, their exports to $U$ decline ($-0.4$ percent, panel J) because dollar prices to $U$ change by little so there is no significant positive expenditure switching effect, and the decline in overall demand in $U$ generates a decline in exports to $U$. Also, because of dollar pricing, there is a sharp decline in exports from $G$ to $R$ ($-0.85$ percent, panel J) and vice versa. This is because the depreciation of these countries’ currencies relative to the dollar makes all imports more expensive, leading to a switch in expenditures away from imported goods.

Figure 2. Impulse Responses to a 25 Basis Point Monetary Tightening in $U$

Notes: Rest-of-world trade is defined as the sum of quantities traded between $G$ and $R$. World trade is defined as the sum of export quantities from all countries.
This is then further accentuated by the (mild) negative impact on consumption from the rise in interest rates in response to the inflationary effect.

As follows from the previous discussion, a monetary tightening in $U$ and the accompanying uniform appreciation of the dollar relative to other countries generate a decline in rest-of-world trade ($-0.83$ percent, panel K), defined as the sum of quantities traded between $G$ and $R$. It also causes a decline in global trade ($-0.73$ percent, panel L), defined as the sum of export quantities from all countries.

**Monetary Policy Shock in Nondominant Currency Country:** We next consider a 25 basis point monetary tightening in a nondominant currency country. Without loss of generality, we set this to be $G$. As depicted in panel C of Figure 3, $G$’s currency appreciates uniformly relative to $U$ and $R$ on impact, and by a magnitude similar to that in panel C of Figure 2. This is because, despite the endogenous change in interest rates in each country (panel B of Figure 3 differs from panel B of Figure 2), the change in the interest rate differential between countries is quite similar, which is what matters for the exchange rate change.

The transmission of the shock to interest rates in $G$ (panel B of Figure 3) is partly muted because the decline in inflation is endogenously contained through the Taylor rule. The negative impact on inflation of $-0.2$ percent (Figure 3, panel D) contrasts with the much smaller effect of an MP shock in $U$ on $U$’s inflation (panel D of Figure 2). This differential response arises from the strong pass-through of the appreciation of $G$’s currency into its import prices. The rise in interest rates in $G$ leads to a decline in output ($-0.6$ percent, panel E). While pass-through into import prices (in $G$’s currency) is high ($-0.6$ percent, panel H), pass-through into export prices (in destination currency) is low. Consequently, there is only a small negative impact on exports from $G$ ($-0.05$ percent, panel J), in contrast to the large negative impact of an MP tightening in $U$ on $U$’s exports (panel I of Figure 2). While exports are not responsive, there is a significant increase in imports into $G$ from $U$, and $R$ through the expenditure switching channel following the depreciation of their currencies relative to $G$’s (panel I of Figure 3). The terms-of-trade are stable, as in the case of the MP shock in $U$ (panel G of Figure 3).

Since exports from $U$ and $R$ to $G$ increase significantly, while exports out of $G$ decline only marginally, the monetary tightening in $G$ is associated with an expansion in global trade (panel L of Figure 3), and almost no effect on rest-of-world trade (gross trade between $U$ and $R$, panel K).

II. Global Empirical Evidence

This section tests the model predictions derived in Section ID, using bilateral trade volumes and unit values for a large number of countries. We show that, consistent with DCP, the US dollar plays an outsized role in driving international trade prices and quantities. We first document that bilateral terms-of-trade are essentially uncorrelated with bilateral exchange rates. Next, we demonstrate that the bilateral (importer versus exporter) exchange rates matter less than the exchange rate vis-à-vis the US dollar for pass-through and trade elasticities of the average country in our sample. We also find the euro to be much less important than the dollar. The effects of the dollar are stronger when the importing country has a higher fraction
of trade invoiced in dollars. The dollar’s role is greatest for trade between emerging market pairs, consistent with their higher reliance on dollar pricing. Finally, we show that the overall strength of the US dollar is a key predictor of gross trade and producer/consumer price inflation in the rest of the world.

A. Data

The core of our dataset consists of panel data on bilateral trade values and volumes from UN Comtrade (2017). UN Comtrade provides detailed annual customs data for a large set of countries at the HS 6-digit product level with information about the destination country, dollar value, quantity, and weight of imports and exports. This dataset makes it possible to compute volume changes over time for each product, and use the value data to infer unit values. Once unit values are calculated, we com-
pute chained Fisher price indices to aggregate up from the product level to the bilateral country level. We focus entirely on data for noncommodity goods, except noted otherwise. Given the inherent difficulty in drawing a line between commodities and noncommodities, we define commodities fairly broadly as HS chapters 1–27 and 72–83, which comprise animal, vegetable, food, mineral, and metal products.

The biggest challenge for constructing price and volume indices using customs data is the so-called unit value bias. Unit values, calculated by dividing observed values by quantities, are not actual prices. Even when there is no price change, unit values can change due to compositional shifts. To take a stab at correcting for this bias, we follow the methodology developed by Boz, Cerutti, and Pugacheva (2019). Specifically, we eliminate 6-digit products with a unit value variance higher than a threshold as those observations are more likely to be biased. To check whether this provides a sufficient fix, we compare our Comtrade estimated price indices with those reported by the Bureau of Labor Statistics (BLS) based on actual import prices for the United States. We find that our indices track the BLS import price indices fairly well. Results of this comparison, further details of Comtrade data construction as well as sources of other macroeconomic data are provided in online Appendix Section A.1.

B. Terms-of-Trade and Exchange Rates

We first relate bilateral terms-of-trade to bilateral exchange rates using panel regressions (testable implication (i)). In this subsection, a cross-sectional unit is defined to be an unordered country pair, so that both trade flows between two countries \( i \) and \( j \) are associated with the cross-sectional unit \( \{i,j\} \). Recall that \( p_{ij} \) denotes the (log) price of goods exported from country \( i \) to country \( j \) measured in currency \( j \), \( e_{ij} \) the (log) bilateral exchange rate between country \( i \) and country \( j \) expressed as the price of currency \( i \) in terms of currency \( j \), and \( \text{tot}_{ij} = p_{ij} - p_{ji} - e_{ij} \) the (log) bilateral terms-of-trade, defined as the ratio of import prices to export prices (measured in the same currency). Moreover, let \( \text{ppi}_{ij} \) denote the (log) ratio of the producer price index (PPI) in country \( i \) divided by PPI in country \( j \), with indices expressed in the same currency.

We consider regressions of the following form:

\[
\Delta \text{tot}_{ij,t} = \lambda_{ij} + \delta_t + \sum_{k=0}^{2} \beta_k \Delta e_{ij,t-k} + \sum_{k=0}^{2} \theta_k \Delta \text{ppi}_{ij,t-k} + \varepsilon_{ij,t},
\]

where \( \lambda_{ij} \) and \( \delta_t \) are dyad (i.e., country pair) and time fixed effects. Regression equation (20) relates the growth rate of the bilateral terms-of-trade to the growth rate of the bilateral nominal exchange rate (and lags). As discussed in Section ID, if exporting firms set prices in their local currencies as in PCP and prices are sticky, the contemporaneous exchange rate coefficient \( \beta_0 \) should equal 1. If instead exporting firms set prices in the destination currency as in LCP and prices are sticky, the contemporaneous exchange rate coefficient should be \(-1\). If most prices are invoiced in US dollars and are sticky in nominal terms, the coefficients \( \beta_k \) should be close to zero. As indicated in equation (20), some of our specifications control for lags 0–2 of the growth rate of the ratio of PPI in both countries, since firms’ optimal reset prices should fluctuate with domestic cost conditions.
We consider both unweighted and trade-weighted regressions. To obtain trade weights, for each dyad and year, we compute the share of world noncommodities trade value (in dollars) attributable to that dyad. Then, for each dyad, we compute the average share across the years 1992–2015.

In line with DCP, we find that bilateral exchange rates are virtually uncorrelated with bilateral terms-of-trade. The results of the panel regressions are shown in Table 2. If we do not control for relative PPI, the regression results indicate that the contemporaneous effect of the exchange rate on the terms-of-trade is positive. While the sign is consistent with PCP, the magnitude is not, as the 95 percent confidence interval equals [0.02, 0.05] in the unweighted regression, and [0.04, 0.13] in the weighted regression.\(^\text{12}\) The coefficients on the lags (not reported) are also small in magnitude. When controlling for relative PPI, the point estimates of the coefficients on the bilateral exchange rate shrink further toward zero, and confidence intervals remain narrow. Hence, our results lend strong support to DCP: the terms-of-trade are unresponsive to bilateral exchange rates.

Although the lack of correlation could in principle be consistent with a world of 50 percent PCP and 50 percent LCP, the next subsections refute that possibility. In addition, while the lack of correlation is consistent with any currency being a dominant currency, we provide evidence next that the major dominant currency is indeed the dollar. The stability of the terms-of-trade for the average country in our sample cannot be explained by a model with flexible prices and strategic complementarities in pricing as in Atkeson and Burstein (2008) and Itskхoki and Mukhin (2017) because, as we show next, the import pass-through into destination country prices at-the-dock is high, while that into consumer or producer prices, reported in online Appendix Section A.2.2, is an order of magnitude smaller, contrary to the presence of strong complementarities in pricing.

Lastly, online Appendix Section A.2.1 demonstrates that the terms-of-trade are nearly uncorrelated with the bilateral exchange rate across all advanced/emerging economy trade flows.

\(^{12}\) Attenuation bias is not a worry in this context, since the explanatory variables of interest (exchange rates) are precisely measured, except perhaps for time aggregation issues at the annual frequency.
C. Exchange Rate Pass-Through into Prices

Next, we relate international prices and exchange rates (testable implication (ii)). Exchange rate pass-through regressions are reduced-form regressions that relate price changes to exchange rate changes and other control variables relevant for pricing. We follow the literature and estimate the standard pass-through regression as described in Burstein and Gopinath (2014). In the rest of this section, the cross-sectional unit is an ordered country pair \((i,j)\). We estimate

\[
\Delta p_{ij,t} = \lambda_{ij} + \delta_t + \sum_{k=0}^{2} \beta_k \Delta e_{ij,t-k} + \sum_{k=0}^{2} \beta_k^S \Delta e_{sj,t-k} \\
+ \sum_{k=0}^{2} \eta_k \Delta e_{ij,t-k} \times S_j + \sum_{k=0}^{2} \eta_k^S \Delta e_{sj,t-k} \times S_j + \theta' X_{i,t} + \varepsilon_{ij,t},
\]

where \(\lambda_{ij}\) and \(\delta_t\) are dyadic and time fixed effects; \(X_{i,t}\) are other country \(i\) controls, namely the change in the (log) producer price index of the exporting country \(i\) measured in currency \(i\) (and two lags).\(^{13}\) We have modified the textbook pass-through regression by including the dollar exchange rate, i.e., the log price \(e_j^\$\) of a US dollar in currency \(j\), alongside the bilateral exchange rate, as suggested in Section ID. Lastly, we interact the bilateral and dollar exchange rates with the importing country’s dollar invoicing share \(S_j\). We consider different versions of this general specification, omitting dollar exchange rates and/or interaction terms.

As a benchmark, the estimates from bilateral pass-through regressions on bilateral exchange rates (i.e., omitting the dollar exchange rates and interaction terms) are reported in columns 1 and 4 of Table 3. The two columns correspond to unweighted and trade-weighted regressions, respectively.\(^{14}\) According to the regression estimates, when country \(j\)’s currency depreciates relative to country \(i\) by 10 percent, import prices in country \(j\) rise by 8 percent, suggestive of close to complete pass-through at the one-year horizon.\(^{15}\) The second and third lags (not reported) are economically less important.

Columns 2 and 5 report estimates from regressions that include the dollar exchange rate in addition to the bilateral one. Including the dollar exchange rate sharply reduces the relevance of the bilateral exchange rate. It knocks the coefficient on the bilateral exchange rate from 0.76 to 0.16 in the unweighted regression, and from 0.77 to 0.34 in the weighted regression. Instead, almost all of the effect is absorbed by the dollar exchange rate.\(^{16}\) Notice that, due to our inclusion of time fixed effects, the apparent dominance of the dollar cannot be an artifact of special conditions that may apply in times when the dollar appreciates or depreciates against all other currencies, for example due to global recessions or flight to safety.

\(^{13}\) Online Appendix Section A.2.5 shows that our results are robust to adding importer PPI and GDP growth as additional control variables.

\(^{14}\) Henceforth, the trade weights are given by the average (across the years 1992–2015) share of world noncommodities trade value attributable to an ordered dyad \((i,j)\).

\(^{15}\) With year fixed effects this should be interpreted as fluctuations in excess of world annual fluctuations.

\(^{16}\) In the literature, unilateral exchange rate pass-through is sometimes estimated using a Vector Error Correction Model (VECM) that allows for co-integration between price levels and exchange rates. However, Burstein and Gopinath (2014, p. 403) finds VECM results to be highly unstable across specifications, and this issue is likely to be compounded by measurement error in our bilateral data.
in asset markets. Online Appendix Section A.2.5 shows that our results are robust to the choice of time sample, including removing the post-2008 period.

The cross-dyad heterogeneity in pass-through coefficients is related to the propensity to invoice imports in dollars. Columns 3 and 6 interact the dollar and bilateral exchange rates with the share of invoicing in dollars at the importer country level, as in regression equation (21). Notice that we do not have data on the fraction of bilateral trade invoiced in dollars, so we use the importer’s country-level share as a proxy. As expected, the import invoicing share plays an economically and statistically significant role for the dollar pass-through. Depending on whether we use trade weights, the regression results indicate that increasing the dollar invoicing share by 10 percentage points causes the contemporaneous dollar pass-through to increase by 3.5–7.6 percentage points. The $R^2$ values of the panel regressions are substantially improved by adding the invoicing share interaction terms.

Figures 4 and 5 depict the regression results visually in the form of impulse response functions. Figure 4 shows the impulse responses of the bilateral import price level. The top row shows unweighted regression results, the bottom row uses trade weights as described above. The left column shows the bilateral pass-through in the specifications without the dollar exchange rate, while the right column compares the bilateral and dollar pass-throughs in specifications with both exchange rates. Figure 5 illustrates the pass-through heterogeneity as a function of the invoicing share $S_j$, as implied by the regression specifications with interactions. The figure focuses on three dollar shares: $S_j = 0.13$ (corresponding to Switzerland), $S_j = 0.59$ (Turkey), and $S_j = 0.88$ (Argentina). As depicted in Figure 5, dollar pass-through is highest for Argentina with the largest dollar invoicing share and the least for Switzerland with its low dollar share. In the trade-weighted regressions (bottom row of Figure 5), dollar pass-through is lower than bilateral pass-through for Switzerland, and that ranking is flipped for the case of Turkey and Argentina.

Online Appendix Section A.2.1 shows that dollar dominance holds up qualitatively across flows between different country groups, advanced or emerging.

Notes: The first (last) three columns use unweighted (trade-weighted) regressions. All regressions include two $\Delta ER$ lags, lags 0–2 of exporter $\Delta PPI$, and time fixed effects. Standard errors clustered by dyad.
Although flows between emerging markets exhibit stronger dollar dominance, our results are not limited to flows involving emerging markets.\footnote{These facts are in line with the results in Table 3 for regressions that interact with the dollar invoicing share, since emerging markets tend to have higher dollar invoicing shares.}

### D. Trade Volume Elasticity

Having demonstrated the outsized role of the US dollar for international prices, we now show that the dollar also dominates the bilateral exchange rate when predicting bilateral trade volumes (testable implication (iii)). Table 4 shows the results from panel regressions of trade volumes on bilateral and dollar exchange rates. Let $y_{ij}$ denote the log volume of goods exported from country $i$ to country $j$. Our volume regressions take the same form as in the price pass-through regression, equation (21), except that the dependent variable is now the log growth rate $\Delta y_{ij,t}$ of bilateral trade volumes, and the extra controls $X_{j,t}$ (here indexed by $j$ rather than $i$) consist of the log growth rate of real GDP (and two lags) for the importing country $j$. These regressions do not capture structural demand elasticity parameters, since we do not attempt to control for all relevant relative prices, and the importer’s GDP growth is
an imperfect proxy for the level of import demand. In particular, we cannot simply add importer × year fixed effects since these would absorb the dollar exchange rate. Hence, our results will invariably conflate expenditure switching and shifts in aggregate import demand. The correct interpretation is to view these regressions as predictive relationships that may inform potential structural estimation exercises. Nevertheless, we will refer to the coefficients on exchange rates as “trade elasticities” for simplicity.

The volume regressions underline the dominant role played by the US dollar. As in the case of the price pass-through regressions, adding the dollar exchange rate to the volume regressions knocks down the coefficient on the bilateral exchange rate by a substantial amount. The contemporaneous elasticity for the dollar exchange rate is about \(-0.19\) to \(-0.13\) across specifications, while the elasticity for the bilateral exchange rate is an order of magnitude smaller. Unlike the price pass-through regressions, the interactions of exchange rate changes with the importer’s dollar invoicing share are mostly imprecisely estimated here.

Figure 5 visually depicts the regression results in the form of impulse responses. The figure shows the response of the level of bilateral trade volume to exchange rate
shocks. The right column shows results from regressions with both bilateral and dollar exchange rates. It is apparent from the figure that the dollar exchange rate has a much more negative impact effect than the bilateral exchange rate. Yet, the figure also shows that the effect of either exchange rate on the level is essentially neutral at horizons of 1–2 years. One potential explanation is that the ratio of import prices to domestic prices adjusts with a lag to exchange rate changes, implying that a year after the initial shock, relative prices faced by consumers are mostly unchanged compared to the period before the shock. However, we show in online Appendix Section A.2.5 that this particular finding is driven by the early years in our sample, as results on the 2002–2015 subsample point toward a large and persistent negative effect of dollar appreciations on the volume of bilateral trade.

Online Appendix Section A.2.1 confirms that the contemporaneous trade elasticity of the dollar dominates the bilateral exchange rate elasticity in most breakdowns of emerging/advanced economy trade flows. Overall, the data indicate that a substantially negative dollar elasticity, coupled with a smaller bilateral exchange rate elasticity, is a common feature to emerging and advanced economy trade flows.

E. Trade Flows to and from the United States

The data are consistent with an additional key prediction of DCP: trade flows with the United States are special (testable implications (ii)–(iii)). Specifically, we show that bilateral exchange rate pass-through into US export prices (in the destination currency) is complete and immediate, while US import prices (in dollars) are insensitive to bilateral exchange rates. Moreover, US import volumes are insensitive to the bilateral exchange rate, as predicted by theory.

Figure 7 shows impulse response functions of import prices for goods flowing from or to the United States. These figures are obtained from panel regressions as in the baseline unweighted fixed effects specifications in Section IIC, except we drop the dollar exchange rate (but preserve the time fixed effects). Consistent with the

very high fraction of US exports and imports being invoiced in dollars (97 percent and 93 percent, respectively), bilateral exchange rate pass-through into prices is 100 percent on impact for US exports and close to zero for US imports.

**Table 5** confirms that US import volumes are insensitive to bilateral exchange rates, unlike the imports of the rest of the world from the United States. We run a fixed effects regression of trade volume growth on lagged bilateral exchange rates, importer GDP, and year fixed effects, as in specifications (1) and (4) of Table 4. Here, however, we additionally interact all right-hand-side variables with an indicator for whether the importing country is the United States. When the importing country is not the United States, the within-year bilateral trade volume response is estimated at −0.12 percent (unweighted) following a 1 percent depreciation of the importer currency, similar to the all-country regression in Table 4. In contrast, we find US imports to be completely insensitive to the bilateral exchange rate on impact, with an implied contemporaneous import volume response of 0.003 percent following a 1 percent depreciation of the dollar. The difference between the contemporaneous import elasticity for the United States versus that for the rest of the world is highly significant. Hence, the data indicate that US trade balance adjustment following exchange rate movements occurs primarily through exports rather than imports, a consequence of the predominance of dollar invoicing in US trade.

**Figure 6. Average Trade Elasticity**

*Notes:* Impulse responses of bilateral volume to bilateral $e_{ij,t}$ and US$ e_j,t$ exchange rates. Based on regressions in Table 4 without interactions. Top row: unweighted regression; bottom row: trade-weighted. Left column: specifications (1) and (4); right column: specifications (2) and (5). Error bars: 95 percent confidence intervals, clustering by dyad.
Underscoring the quantitative significance of DCP, we argue now that the dollar has substantial predictive power for aggregate trade among countries in the rest of the world (testable implication (iv)). That is, the dollar is important for predicting global trade, even when excluding countries’ direct trade with the United States. Specifically, a 1 percent US dollar appreciation against all other currencies in the world predicts a 0.6 percent decline within a year in the volume of total trade between countries in the rest of the world, holding constant various proxies for the global business cycle.

We measure the elasticity of rest-of-world trade volume to the dollar by aggregating up from our richest bilateral panel regression specification. This produces results that exploit our panel dataset, unlike a simple annual time series regression of global

Notes: ImpUS is in indicator for whether importing country is the United States. Both regressions include two ΔER lags, lags 0–2 of importer ΔGDP, and time fixed effects, as well as interactions of these variables with ImpUS. Standard errors clustered by dyad.

F. Effect of US Dollar on Rest-of-World Trade and Inflation

Figure 7. Price Pass-Through: Flows to and from United States

trade on an effective dollar exchange rate index. Consider the following regression model with bilateral, dollar, and euro exchange rates, as well as interactions with dollar and euro import invoicing shares:

\[
\Delta y_{ij,t} = \sum_{k=0}^{2} \left( \beta_k + \eta_k \left( 1 - S_j - S_j^e \right) \right) \Delta e_{ij,t-k} + \sum_{k=0}^{2} \left( \beta_k^S + \eta_k^S S_j \right) \Delta e_{j,t-k}^S + \sum_{k=0}^{2} \left( \beta_k^€ + \eta_k^€ S_j^€ \right) \Delta e_{j,t-k}^€ + \lambda_{ij} + \theta' X_{ij,t} + \varepsilon_{ij,t}.
\]

Here \( S_j \) and \( S_j^e \) are the importer’s country-level dollar and euro invoicing shares, respectively, and \( \lambda_{ij} \) is a dyad fixed effect. Because we are interested in the effect of a dollar appreciation against all other currencies, we do not control for time fixed effects. Instead, we control for several proxies for the global business cycle, as described in online Appendix Section A.2.3, except here we exclude world export volume growth. \( X_{ij,t} \) also includes lags 0–2 of importer real GDP growth.

The object of interest is the response of rest-of-world (i.e., ex-US) aggregate trade volume to a 1 percent appreciation of the dollar relative to all other currencies, holding constant the global business cycle. As in equation (19), we consider the weighted average trade elasticity to a dollar appreciation, where we average over all trading pairs in the world, excluding the United States. Consistent with the focus on importers in the rest of this section, our empirical specification in equation (22) assumes that the trade elasticity is heterogeneous across importers but homogeneous across exporters. That is, in the notation of equation (19), the trade elasticity at lag \( k \) with respect to the dollar exchange rate is given by \( \sigma_{ij} = \sigma_j = \beta_k^S + \eta_k^S S_j \). Let \( w_j \) denote country \( j \)'s total noncommodity import value from all countries except the United States in some reference year, normalized so that \( \sum_{j \neq S} w_j = 1 \). Then the \textit{ceteris paribus} effect of a 1 percent dollar appreciation on \( \sum_{j \neq S} w_j \Delta y_{ij,t} \), the weighted growth of rest-of-world imports from destination \( i \), is given by

\[
\sum_{j \neq S} w_j \left( \beta_k^S + \eta_k^S S_j \right) = \beta_k^S + \eta_k^S \sum_{j \neq S} w_j S_j,
\]

\( k \) years after the appreciation, and this quantity is by assumption the same for each exporter \( i \) other than the United States. Thus, to measure the response of rest-of-world aggregate imports to a dollar appreciation, we simply use the estimated equation (22) to compute the impulse response of trade volume for an importer \( j \) whose US dollar invoicing share happens to equal \( \sum_{j \neq S} w_j S_j \), the weighted average dollar invoicing share.\(^{19}\)

Figure 8 shows that rest-of-world aggregate import volume contracts markedly following an appreciation of the dollar against all other currencies. A 1 percent \textit{ceteris}
Dollar appreciation leads to a 0.6 percent contraction in rest-of-world trade volume within the year (regardless of whether we use unweighted or trade-weighted regressions), and this contractionary effect persists out to at least two years. Recall that the regression controls for various proxies for the global business and financial cycles. While our regression specification cannot be interpreted structurally, the magnitude of the predictive effect underscores the importance of the dollar’s role in world trade. Online Appendix Section A.2.4 shows that the large negative predictive effect of a dollar appreciation on world trade is robust to controlling for the exchange rates of the Swiss franc and Japanese yen. Hence, the central finding in this subsection is not an artifact of conflating periods of overall dollar appreciation with periods of global flight to safety.

Finally, country-level regressions reveal significant dollar pass-through to foreign consumer and producer prices that increases with countries’ dollar invoicing share in imports. Earlier work by Gopinath (2015) provides back-of-the-envelope calculations of dollar exchange rate spillovers on foreign consumer and producer prices based on estimated country-level import price pass-through and the import content of consumption. We take a more direct approach and regress countries’ CPI or PPI on the dollar exchange rate as well as its interaction with the dollar invoicing share in imports using a specification with country and time fixed effects, detailed in online Appendix Section A.2.2. We find the average pass-through of the dollar into CPI (respectively, PPI) to be 11 percent (respectively, 28 percent) within the year, and is higher for countries with a higher dollar invoicing share of imports.
G. Robustness

Our results are robust to many different variations, some of which have already been mentioned in previous sections alongside the description of our benchmark results and summarized here. First, our results are robust when considering trade flows within/ across advanced or emerging market economies (see online Appendix Section A.2.1). In particular, our results are not limited to flows involving emerging markets.

Second, our results are robust to excluding the global financial crisis. Online Appendix Section A.2.5 documents that our headline results are not driven by the global financial crisis starting in 2008. The estimated average exchange rate pass-through and trade elasticity computed on the 1992–2007 sample are almost identical to our baseline Figures 4 and 6. When computing the effect of a uniform US dollar appreciation on rest-of-world trade as in Section IIF, we find even stronger effects during the precrisis period 2002–2007.

Third, online Appendix Section A.2.3 shows that the euro exchange rate is much less quantitatively important than the dollar exchange rate in price and volume regressions. Lastly, online Appendix Section A.2.4 shows that the large negative predictive effect of a dollar appreciation on world trade is robust to further controlling for the exchange rates of the Swiss franc and Japanese yen.

III. Firm-Level Empirical Evidence

We now move from aggregate bilateral data on trade volume and value to firm-level customs data on exports and imports for a small open economy, Colombia. While the global evidence has the virtue of covering 91 percent of world trade, it lacks granularity and the indices are at the annual frequency. To assuage any concerns that our findings may be contaminated by composition effects this section demonstrates that the findings in Section II hold when we define prices and quantities at the firm-10-digit product-country (origin or destination)-quarter (or -year) level. In addition we show that the DCP model matches the dynamic path of price pass-through in the data unlike the competing paradigms. The details of the Colombian data (DANE 2015, DIAN 2015) are relegated to online Appendix Section A.3.

The Colombian currency (peso) is a commodity currency and fluctuations in its value are strongly negatively correlated with fluctuations in commodity prices. Figure 9 displays the relation between the Colombian peso (peso price of the dollar, solid line) and the overall (log) terms-of-trade (dashed line), defined as the log difference between import and export prices. This terms-of-trade is driven primarily by commodity prices. The correlation between the two series is 0.62 and a regression of the overall terms-of-trade on the peso/dollar exchange rate yields a coefficient on the exchange rate of 1.15 ($R^2$ of 0.38). If we focus instead on the noncommodity terms-of-trade (dots-and-dash line) we find that the terms-of-trade is far more stable.

\[ \text{Figure 9 displays the relation between the Colombian peso (peso price of the dollar, solid line) and the overall (log) terms-of-trade (dashed line), defined as the log difference between import and export prices. This terms-of-trade is driven primarily by commodity prices. The correlation between the two series is 0.62 and a regression of the overall terms-of-trade on the peso/dollar exchange rate yields a coefficient on the exchange rate of 1.15 ($R^2$ of 0.38). If we focus instead on the noncommodity terms-of-trade (dots-and-dash line) we find that the terms-of-trade is far more stable.}\]

\[ ^{20}\text{The Colombian peso officially switched to a floating status in 1999. Commodity prices can be considered as exogenous to the economy: while mining output makes up 58.4 percent of total exports for Colombia, it is small relative to world commodity markets. For example, Colombia’s oil production was 1.1 percent of world oil production in 2014.}\]
with a regression coefficient of 0.33 ($R^2$ of 0.36), consistent with the predictions of the model under DCP.\textsuperscript{21}

In the rest of our empirical analysis we focus on manufactured goods, consistent with the approach in Section II, excluding products in the petrochemicals and basic metals industries. We follow the ISIC Rev. 3.1 classification to define which products are manufactures.\textsuperscript{22}

A. Results

We estimate the same pass-through regression of exchange rates into import and export prices (measured in pesos) as in equation (21), omitting interaction terms and time effects, since the latter would absorb the dollar exchange rate. We include firm-industry-country fixed effects, which subsume dyad fixed effects, as well as quarter dummies to account for seasonality.\textsuperscript{23} We add the contemporaneous effect and eight lags of the quarterly log change in the nominal exchange rate of the peso relative to the dollar regardless of origin or destination country. The cumulative estimates $\sum_{s=0}^{k}\beta_s$ and two standard error bands with standard errors clustered at the quarter-year level are plotted in Figure 10. It reports the pass-through into export and import prices (columns) to/from dollarized and non-dollarized countries (rows).

\textsuperscript{21} The TOT(Manuf) is constructed by excluding “traditional” exports/imports such as oil, coal, metals, coffee, bananas, or flowers. Although it does not consist exclusively of manufactured goods, these represent more than 90 percent of the basket.

\textsuperscript{22} As a robustness check we also use the subsample of differentiated products only (instead of the full set of manufactures presented) constructed using the classification of goods by Rauch (1999). This is available in online Appendix Section A.4.

\textsuperscript{23} We also estimate the regression controlling for contemporaneous and eight lags of quarterly log changes in the producer price index in Colombia and in the origin/destination country and our estimates are practically unchanged.
Consistent with DCP, all pass-throughs start out close to one and decline slowly over time. This is the case for both export and import prices and for dollar and non-dollar destinations/origins. In the case of export prices to dollar destinations the contemporaneous estimate is 0.84 and then the cumulative pass-through slowly decreases after two years to 0.56. The estimates are similar in the case of non-dollar destinations. In the case of import prices from dollar origins pass-through is very high, around 1, and the cumulative effect declines to 0.8. For non-dollar origins the estimated pass-through starts at around 0.87 and decreases to 0.49 after two years.

The second set of regressions replicates the regressions in Section II by aggregating data to the annual frequency (the unit of observation remains firm-industry-country fixed effects and quarterly dummies. 95 percent confidence intervals shown with standard errors clustered at the quarter-year level. The sample includes all manufactured products excluding petrochemicals and basic metals industries. Dollarized economies include the United States, Puerto Rico, Panama, Ecuador, and El Salvador. Non-dollarized economies include all other partners, except economies with currencies pegged to the dollar and Venezuela.

Table 7 reports the results from annual quantity regressions. Starting with the dollarized economies, the pass-through to export quantities is insignificantly different from zero. On the other hand, for imports from dollarized economies there is a pronounced decline in quantities imported across all specifications. In the case of the non-dollarized economies, the decline in imports is also significantly negative and, importantly, the relevant exchange rate is the peso/dollar exchange rates as opposed to the bilateral exchange rate. For exports we again have that the relevant exchange rate is the peso/dollar exchange rate.
B. Matching Model and Data

In this section we simulate data for a small open economy calibrated to match the Colombian economy (denoted $H$) that trades with the dominant currency area (denoted $D$ in this section) and the rest of the world (denoted $R$). The model is identical to the one described in Section I except that we modify the budget constraint slightly to include shocks to oil earnings. Specifically the budget constraint takes the form:

\[ P_{j,t} C_{j,t} + \varepsilon_{8_{j,t}} (1 + i_{j,t-1}) B_{j,t}^D + B_{j,t} = W_{j,t}(h) N_{j,t}(h) + \Pi_{j,t} + \varepsilon_{8_{j,t}} B_{j,t+1}^D + \sum_{s \in S} Q_{j,t}(s') B_{j,t+1}(s') + \varepsilon_{8_{j,t}} \zeta_t, \]

where $\zeta_t$ is the dollar value of the endowment of oil. A decline in $\zeta_t$ captures a decline in the price of oil. We capture the relation between $\varepsilon_{8_{H,t}}$ and $\varepsilon_{R_{H,t}}$ using the following reduced-form relation between the two real exchange rates (in logs):

\[ e_{R_{H,t}} + p_{R,t} - p_{H,t} = \eta (e_{8_{H,t}} + p_{8,t} - p_{H,t}) + \varepsilon_{R,t}. \]  

In equation (23), $p_{i,t}$ denotes the (log) consumer price level in country $i \in \{D, R\}$ in its respective currencies, $\varepsilon_{R,t}$ captures idiosyncratic fluctuations in the $D-R$ exchange rate while $\eta$ captures the comovement between the two real exchange rates.
With this flexible specification, we can explore separately how fluctuations in \( H_t \) and \( RH_t \) impact prices and quantities in \( H \), under different pricing paradigms.\(^{24}\)

The model therefore features three sources of fluctuations: productivity shocks \( a_t \), endowment shocks \( \zeta_t \) that capture the exogenous fluctuations in the price of oil, and exogenous shocks to the $-R$ exchange rate \( \epsilon_{R_t} \). These shocks follow autoregressive processes:

\[
\begin{align*}
\zeta_t - \bar{\zeta} &= \rho_\zeta (\zeta_{t-1} - \bar{\zeta}) + \epsilon_{\zeta,t}, \\
\epsilon_{R,t} &= \rho_R \epsilon_{R,t-1} + \epsilon_{R,t},
\end{align*}
\]

where \( \bar{\zeta} \) is the steady-state value of the commodity price, and \( \epsilon_{\zeta,t} \) are serially independently distributed innovations. We allow the productivity and commodity price innovations to be correlated, and denote \( \rho_{a,\zeta} = \text{corr}(\epsilon_{a,t}, \epsilon_{\zeta,t}) \).

We use a combination of calibration and estimation to parameterize the model, the details of which are provided in online Appendix Section A.5. We match several moments in the data, including price pass-through regression coefficients as well as estimated parameters in the time series processes for Colombia’s real exchange rate,

\[^{24}\text{An alternative setup would be to allow for the small open economy to borrow internationally in both}\ $\text{and}\ R\text{ currencies. Then, even if interest rates in the}\ $\text{and}\ R\text{ do not change, shocks that drive a wedge in the UIP conditions (commonly used to capture risk premia shocks) for each of the two currencies will generate fluctuations in}\ \epsilon_{SH,t}/\epsilon_{RH,t}.\]

---

**Table 7—Trade Elasticity with Respect to Exchange Rate, Annual Data**

| Panel A. Exports | Dollarized | | Non-dollarized | |
|------------------|------------|---------------|---------------|
| \( \Delta e_{SH,t} \) | \( \Delta y_{H,t} \) | \( \Delta y_{H,t} \) | \( \Delta y_{H,t} \) |
| (1) | (2) | (3) | |
| \( \Delta e_{SH,t} \) | \(-0.763\) | \(-0.0553\) | \(0.212\) | \(0.314\) |

| Observations | 529,276 | 808,409 | 519,002 |

**Notes:** All regressions control for PPI, importer GDP, and Firm-Industry-Country fixed effects. Standard errors clustered at the year level. See also caption for Table 6.
value added, and commodity prices. The estimated model is very close to DCP. The export invoicing shares for Colombia are measured in the data directly and is 100 percent for exports to $ and 93 percent for exports to R. The estimated import invoicing shares are 100 percent for imports from $ and 93 percent for those from R. We simulate the parametrized model and plot the pass-through estimates from the estimated model, and counterfactual DCP, PCP, and LCP models against the estimates from the data. In the case of the latter three we force the invoicing shares to take the extreme values of each of the paradigms, keeping all other parameter values unchanged.

**Dynamics of Pass-Through:** Figure 11 reports the values for price pass-through for dollar destinations and Figure 12 for non-dollar destinations. In each figure, export price pass-through are reported in the left column, and import price pass-through in the right column. Each row corresponds to a different model: the estimated model (top row), a full DCP counterfactual (second row), a PCP counterfactual (third row), and a LCP counterfactual (last row). Large solid circles for the pass-through of export and import prices to/from various destinations at impact represent values that were used in moment matching. The pass-through at other lags were not used in estimating parameters.

As is evident, the estimated model replicates the pass-through estimates at various lags for export prices to $ and R and for import prices from $ quite closely. While the match is less good for import prices from R, we still obtain that pass-through starts high and declines gradually. Inspecting the different rows, it is immediate that the estimated model is very close to DCP, and very different from a PCP or LCP counterfactual. PCP implies low initial pass-through into export prices, which then gradually increases over time, as prices are sticky in the exporting currency. LCP implies low pass-through into import prices, which then increases over time, as prices are sticky in the importing currency. In the case of non-dollar trading partners we similarly observe that DCP outperforms both PCP and LCP.

**Relevance of Bilateral Exchange Rates:** The estimated model also matches the empirical fact that bilateral exchange rates show up as large and significant when they are the only exchange rate control in price or quantity regressions (for non-dollar destinations and origins), but drop significantly as a predictor of prices once the dollar exchange rate is also included in the specification. This is reported in Table 8 for price pass-through regressions and in Table 9 for trade elasticity regressions. The estimated model generates a weak expansion in exports to $ destinations following a depreciation and a more pronounced contraction in imports from both $ and R consistent with the empirical evidence in Table 7. Exports to R are negatively impacted by depreciations relative to the dollar. Here again the dollar exchange rate is a major predictor of quantities for non-dollar regions.

**Importance of Nonzero α and Γ:** Finally, Figure 13 explores the role of strategic complementarities in pricing and imported input use in production for our results. It contrasts the pass-through estimates when Γ (the markup elasticity) and α
(the intermediate input share) are both set to 0 relative to the benchmark of $\Gamma = 1$ and $\alpha = 2/3$ (dashed line). This imposes constant markups and a production function with labor only. The left column reports the dynamic pass-through of export prices, and the right column that of import prices. The top row reports export and import prices to/from $\$ \text{ and the bottom row to/from } R$. Export price pass-through into $H$ prices declines by one-half at the one-year horizon when $\Gamma$ and $\alpha$ are both set.

equal to 0 (line with solid circles), compared to the data and the benchmark model predictions. In the case of import pass-through the difference is smaller (as to be expected given that the marginal costs of foreign firms are taken as exogenous), but in all cases the model’s match with the data is the best under the benchmark specification. Strategic complementarities in pricing and imported input use in production are important factors controlling the (slow) dynamic of price pass-throughs.

IV. Conclusion

Most trade is invoiced in very few currencies. Building from this key observation, this paper presents a dominant currency paradigm characterized by three key features: pricing in a dominant currency, strategic complementarities in pricing, and imported input use in production. We integrate these new elements into a model of small or large open economies. The model is used to understand the consequences of home or dominant monetary policy shocks on exchange rates and fluctuations. The model predicts (i) stability in the terms-of-trade; (ii) that the dollar (i.e., dominant) exchange rate dominates bilateral exchange rate in price pass-through and trade elasticity regressions outside the United States; (iii) high and persistent pass-through into export and import prices; (iv) that global trade outside the United States declines when the dollar appreciates.

We validate empirically these predictions using two sources of data. First, at the aggregate level, we use a newly constructed global bilateral trade dataset that covers 91 percent of world trade. Then, we test the implications of the theory using micro-data at the firm-product-destination-year level from Colombia. All the key implications of the DCP are confirmed empirically, while other pricing paradigms are soundly rejected.

Looking forward, the dominant currency paradigm has striking implications for economic policy and its spillovers. For instance, we demonstrate that the inflation-output trade-off in response to a monetary policy shock is seriously impaired under DCP compared to the usual case of PCP. Monetary policy shocks in the dominant currency country also have strong spillovers to the rest of the world, while the converse is not true: the dominant currency country is largely insulated from the inflationary consequences of fluctuations in its currency, which are absorbed instead into prices and trade in the rest of the world. This has important implications for monetary policy, which are explored at greater length in Casas et al.

Notes: Exchange rate pass-through into export and import quantities to/from dollarized and non-dollarized economies. Regressions have the bilateral exchange rate, the dollar exchange rate, and the level of demand as controls.
For instance, under DCP, a small open economy’s optimal monetary policy is no longer able to attain both zero producer price inflation and zero output gap in circumstances where producer currency pricing would.

Our framework takes the invoicing currency choice as given. Yet, we have been careful to point out that most of our results would hold even with endogenous currency invoicing. First, some ingredients from our model, namely imported input use in production and strategic complementarities in pricing, are precisely those that would give rise endogenously to dominant currency in pricing. This is demonstrated by Gopinath, Itskhoki, and Rigobon (2010) in a partial equilibrium environment and more recently by Mukhin (2018) in a general equilibrium setting. Second, Gopinath, Itskhoki, and Rigobon (2010) shows that firms choose to price in currencies in which their reset prices are most stable, i.e., the desired medium-run pass-through into prices (expressed in the invoicing currency) is low. In other words, our empirical findings will continue to be relevant in an environment with endogenous currency choice.

Taking a step back, our paper confirms that the dominance of the US dollar is pervasive, from the structure of external balance sheets (Gourinchas and Rey 2014), the currency composition of private portfolios (Maggiori, Neiman, and Schreger 2018), the choice of anchor currency (Ilzetzki, Reinhart, and Rogoff 2017) and trade invoicing, with important and complex interactions which we are only starting to explore (e.g., Gopinath and Stein 2018).
