ABSTRACT: Accurately characterizing net evasion of elemental mercury (Hg⁰) from marine systems is essential for understanding the global biogeochemical mercury (Hg) cycle and the pool of divalent Hg (HgII) available for methylation. Few high resolution measurements of Hg⁰ are presently available for constraining global and regional flux estimates and for understanding drivers of spatial and temporal variability in evasion. We simultaneously measured high-resolution atmospheric and surface seawater Hg⁰ concentrations as well as the total Hg distribution during six cruises in the West Atlantic Ocean between 2008 and 2010 and examined environmental factors affecting net Hg⁰ formation and evasion. We observed the lowest fraction of Hg as Hg⁰ (7.8 ± 2.4%) in the near-coastal and shelf areas that are influenced by riverine inputs. Significantly higher %Hg⁰ observed in open ocean areas (15.8 ± 3.9%) may reflect lower dissolved organic carbon (DOC) in offshore environments, which is known to affect both the reducible HgII pool and redox kinetics. Calculated Hg⁰ evasion changed by more than a factor of 3 between cruises (range: 2.1 ± 0.7 to 6.8 ± 5.1 ng m⁻² h⁻¹), driven mainly by variability in Hg⁰ and wind speed. Our results suggest that further mechanistic understanding of the role of DOC on Hg redox kinetics in different types of marine environments is needed to explain variability in Hg⁰ concentrations and improve global estimates of air–sea exchange.

INTRODUCTION

Oceanic evasion of gaseous elemental Hg (Hg⁰) accounts for ∼1/3 of annual global atmospheric Hg emissions and reduces the amount of HgII available for methylation, a neurotoxin that bioaccumulates in marine fish. Air–sea exchange of Hg⁰ extends the lifetime of Hg in actively cycling surface reservoirs and enhances the global distribution of anthropogenic sources. Few high resolution measurements of Hg⁰ are presently available for constraining global and regional flux estimates and for understanding drivers of spatial and temporal variability in evasion. Here we use data from six cruises in two contrasting regions of the western Atlantic Ocean to examine variability in Hg⁰ concentrations and air–sea exchange in coastal, shelf, and open ocean waters.

Few prior studies of the distribution of Hg⁰ in coastal and open ocean waters have visited the same location more than once. Different water masses in open ocean regions exhibit substantial variability in subsurface Hg concentrations as do surface waters due to seasonal mixing with subsurface waters, inputs from atmospheric deposition, and losses from Hg⁰ evasion. Longer term variations in seawater Hg concentrations reflect the impact of changes in anthropogenic inputs and also affect the extent of Hg⁰ evasion at the surface. Higher surface ocean productivity increases Hg removal through particle scavenging and may also enhance biological Hg⁰ reduction.

In coastal environments, temporal differences in Hg concentrations are more pronounced than in the open-ocean both seasonally due to variability in freshwater inputs and changes in anthropogenic inputs at ocean margins over longer time scales. Elevated total Hg concentrations in coastal regions reflect inputs from rivers, submerged groundwater discharge, and point sources such as wastewater and industrial effluents.

Net Hg⁰ concentrations in seawater reflect the influence of environmental factors such as wind speed, temperature, photochemistry, productivity, microbial activity on redox chemistry, and the rate of gas transfer at the air–sea interface. Reduction of HgII to Hg⁰ is driven by a combination of photolytic and biotic processes, while conversion of Hg⁰ back to HgII occurs by both photochemical and dark oxidation. Both the size of the reducible HgII pool and the balance of these redox reactions determines the extent of net reduction in seawater. Prior research shows the
reducible Hg²⁺ pool is affected by the relative stability of Hg²⁺ complexes with both inorganic and organic ligands.

The main objective of this study is to better understand spatial and temporal variability in Hg⁰ concentrations and fluxes across coastal, shelf, and open-ocean waters. To do this, we measured short-term and interannual variability in Hg⁰ concentrations and examined associated environmental drivers of changing concentrations and fluxes. Here we present high resolution simultaneous measurements of atmospheric and oceanic Hg⁰, Hg speciation, wind speed, temperature, salinity, and in situ fluorescence from six cruises in the Gulf of Maine, the New England Shelf, the continental slope region, and the Sargasso Sea between 2008 and 2010.

### METHODS

Figure 1 shows the cruise tracks where we simultaneously measured total gaseous atmospheric Hg and dissolved gaseous Hg, and Table 1 provides details of cruises and sampling dates. We assume dissolved gaseous Hg in surface seawater is mainly Hg⁰ because studies have shown that it generally contains <5% dimethylmercury. On most cruises, the ship was continuously moving except when sampling, which allowed for the collection of data to examine small scale variability in concentrations and speciation. Atmospheric and aqueous Hg⁰ data were collected continuously in the Gulf of Maine, New England shelf, and continental slope regions (denoted AUG08-S and OCT09-S for the August 2008 and October 2009 cruises, respectively) and in the Sargasso Sea (September 2008: SEP08-O; June 2009: JUN09-O; September 2009: SEP09-O; August 2010: AUG10-O). Ancillary data on wind speed, salinity, surface water temperature, and in situ fluorescence (a proxy for Chla) were also collected from the ship’s surface water intake.

Surface seawater samples for total Hg analysis were collected with trace-element clean Go-Flo or Ex-Niskin bottles suspended from a nonmetallic hydrowire, either singly or with a rosette. Samples were processed on board in either a clean van or a sheet-plastic “bubble” supplied with HEPA filtered air. Standard trace-metal-free sampling techniques were followed at all times. Additional details on sampling protocols can be found in Hammerschmidt et al. and Lamborg et al. Water samples for analysis of dissolved Hg species (<0.2 μm) were filtered using acid-washed, plastic vacuum filtration units (GE polycarbonate (PCTE) membranes (0.2 μm)), transferred to glass storage bottles, preserved with 0.5% HCl (trace metal grade), and refrigerated. Unfiltered samples were transferred directly from 2 L Teflon (FEP) holding bottles to glass storage bottles and preserved in the same way. We analyzed total Hg using 100–200 mL aliquots of filtered or unfiltered water digested chemically with 0.2 mL of bromine monochloride (BrCl) per 100 mL of sample, and subsequently excess oxidant was neutralized with 0.1 mL of hydroxylamine hydrochloride (NH₂OH·HCl) per 100 mL of sample (12% weight/volume solution). Sample Hg was reduced to Hg⁰ with stannous chloride (SnCl₂) and quantified by cold vapor atomic fluorescence spectrometry (CVAFS) using a TEKRAN 2500. Based on two separate assessments, the average method detection limit is 0.15 pM, and the average reagent blank (includes BrCl, NH₂OH·HCl, and trace metal HCl at 0.5%) is 0.35 pM. We regularly participate in international intercalibration exercises (e.g.,) for all Hg species which have validated our analytical methods.

We measured atmospheric Hg⁰ with 5 min resolution using a Tekran 2537A mercury vapor analyzer. The instrument was calibrated daily using the internal calibration source and had a detection limit of <0.2 ng m⁻³. For aqueous Hg⁰, we collected seawater from the ship’s intake at 5 m depth and used the automatic continuous equilibrium system with a 5-min temporal resolution described in detail in Andersson et al. Instrument calibration and detection limit were as described for atmospheric measurements. We aggregated all high-resolution measurements including underway measure-

ments of salinity, temperature, and in situ fluorescence into 1-h averages for statistical analyses. Averaging over 1 h is reasonable, as the short-term variability in the measurements was small (<3% variability typically for 1 h, n = 12). Additionally, this analytical variability is much less than that found during individual cruises, indicating that the changes observed over longer time scales are not due to analytical factors. Comparison of continuous and manual batch measurements also showed that the underway measurements are consistent with the batch data ($r^2 = 0.85$, $p < 0.001$, $n = 15$), as found by others.\(^50\)

Air–sea fluxes were calculated using the Nightingale et al.\(^{31}\) parametrization for instantaneous wind speeds, Henry’s law coefficient for Hg\(^0\),\(^32\) a temperature-corrected Schmidt number for CO\(_2\),\(^33\) and the Wilke–Chang method for estimation of a temperature and salinity-corrected Hg\(^0\) diffusivity.\(^34\) We selected the Nightingale et al.\(^{31}\) parametrization because it provides a midrange estimate of air–sea exchange.\(^{35,36}\) Other studies have established that variability in estimated Hg\(^0\) evasion across gas-exchange models is generally ±30%,\(^6,16,37,38\) which is much less than the ranges of fluxes calculated here (~300%) due to differences in measured Hg\(^0\), wind speed, and temperature.

### RESULTS

Figure 2 shows measured spatial distributions of filtered total Hg and dissolved aqueous Hg\(^0\). Highest total Hg concentrations were measured on the August 2008 shelf cruise in the Gulf of Maine and on the New England Shelf (Table 2, filtered Hg: 1.3–3.5 pM). Total Hg was significantly lower ($t$ test for paired means: $p < 0.0001$) during the October 2009 cruise in the same region (Table 2, filtered Hg: 0.45–0.89 pM). Total Hg concentrations measured in the Sargasso Sea were in the same range as the October 2009 shelf cruise (Table 2), with the exception of higher concentrations during the August 2010 sampling period (filtered: 1.2–1.6 pM).

Cruise wide average Hg\(^0\) concentrations differed significantly ($t$ test for paired means: $p < 0.0001$) between all cruises (Table 2). Highest Hg\(^0\) concentrations were observed during the August 2008 shelf cruise (160 ± 60 fM) and the August 2010 Sargasso Sea cruise (196 ± 34 fM), and lowest concentrations were measured during the October 2009 shelf cruise (90 ± 24 fM). Variability in seawater Hg\(^0\) concentrations was greater on the shelf and slope (40–400 fM) than in the Sargasso Sea (80–260 fM). We did not find any significant difference in Hg\(^0\) concentrations between night and day (day 06:00–18:00) during any of the cruises.

The fraction of filtered total Hg present as Hg\(^0\) (%Hg\(^0\)) was significantly higher ($t$ test, $p < 0.0001$) in waters with salinities above 34.6 psu (15.8 ± 3.9%) than at lower salinities (7.8 ± 2.4%; <33.8 psu) (Figure S1, Supporting Information). Mean %Hg\(^0\) was very similar for the two shelf/slope cruises (OCT09: S = 8.8% Hg\(^0\) in seawater below 33.8 psu, AUG08-S = 7.6% Hg\(^0\)) despite large differences in total Hg concentrations.

Atmospheric Hg\(^0\) concentrations measured across the four cruises were stable (1.4–1.5 ng m\(^{-3}\)) (Table 2). Marine air concentrations were elevated compared to landbased sites at Appledore Island in the Gulf of Maine and Kejimkujik, Nova Scotia (~1.1–1.2 ng m\(^{-3}\) for the same months as sampling period).\(^39,40\) Likely due to oceanic evasion.\(^12\)

Calculated evasion fluxes ranged from 2.1 to 6.8 ng m\(^{-2}\) h\(^{-1}\) across all cruises (Table 2). As expected, this 3-fold variability is driven mainly by differences in seawater Hg\(^0\) concentrations and wind speeds across the various cruises. The highest overall flux corresponds to the August 2010 sampling period in the Sargasso Sea where elevated seawater Hg\(^0\) concentrations were observed and wind speeds averaged 6.2 ± 2.4 m s\(^{-1}\) (Table 2). Lowest average evasion fluxes were observed in September 2009 in the Sargasso Sea and October 2009 on the shelf when wind speeds and seawater Hg\(^0\), respectively, were lowest among all the cruises.

### DISCUSSION

**Variability in Coastal and Shelf Hg Concentrations.**

The observed ~3-fold difference in total Hg and Hg\(^0\) concentration between the two shelf cruises reflects interannual variability in freshwater inputs. Salinity was lower (e.g., 2.6 psu at Station 2) in August 2008 compared to October 2009 at overlapping sampling stations due to anomalously high rainfall in July of 2008 and correspondingly elevated freshwater

“DL = detection limit. bAverage fluxes calculated using the Nightingale et al.51 model. cBased on monthly averaged reported fluxes calculated using the Wanninkhof et al.55 model. dBased on annually averaged reported flux calculated using the Liss and Merlivat56 model and Wanninkhof et al.55 model, respectively.

discharges. Additional, total suspended solids concentrations (also related to freshwater inputs) were higher in August 2008 (up to 4 mg/L) compared to October 2009 (≤1 mg/L). Typically, freshwater inputs to the Gulf of Maine peak in April and May and are lowest in July–October. However, in August 2008 freshwater inflow was equivalent to peak discharges that generally occur in April and May (Figure S2, Supporting Information). These results highlight differences in marine shelf and slope Hg concentrations attributable to seasonal and interannual variability in freshwater discharges.

Declining total Hg with increasing salinity measured across all stations (R² = 0.36, P < 0.005, n = 25) reflects decreasing inputs from rivers moving from the coast into the open ocean. Total Hg concentrations measured by others in Gulf of Maine tributaries are substantially higher than we observed in marine waters (unfiltered range: 7.8–29.1 pM for the outer Bay of Fundy and up to 93 pM for the contaminated Penobscot river). Sunderland et al.44 estimated that for the entire Gulf of Maine system, on average riverine total Hg accounted for only 5% of total inputs, with the remaining fractions from inflowing oceanographic inputs, atmospheric deposition, and point sources. By contrast, the freshwater content of seawater analyzed here at station 2 ranged from 20% in August 2008 to 10% October 2009 (Figure 1) and accounted for difference of 1.9 pM in total Hg, suggesting a relative contribution of >70% from rivers at this location in August 2008. Harris et al.45 reported similar findings for the Gulf of Mexico where on a system-wide annual basis, total Hg inputs from rivers were a relatively minor contributor but over smaller spatial scales were the dominant contributor to inputs.

Despite relatively greater Hg inputs at coastal margins, total Hg concentrations measured during the October 2009 shelf

\(^a\)NA = not available. \(^b\)Temperature, salinity, and in situ fluorescence showed multicollinearity (variance inflation factor >4) for the October 2009 shelf cruise.

Crus were similar in magnitude to Sargasso Sea values. This can be explained by the higher relative productivity across the nearshore sites in October 2009 (0.28–7.43 mg m\(^{-3}\)) and associated particle Hg removal compared to offshore areas (<0.08 mg m\(^{-3}\)) (Table 2).\(^{46}\) In August 2008 high total Hg concentrations reflected the combination of lower productivity (0.16–3.97 mg m\(^{-3}\)) and elevated freshwater inputs (~20% freshwater input at Station 2). On a global scale, model results suggest that particle-associated Hg\(0\) scavenging from the surface ocean is the main vector for transport to subsurface waters and thus seasonal and interannual variability in productivity is important for characterizing variability in seawater Hg.\(^{13}\)

**Variability in Offshore Total Hg.** Recent surface water total Hg measurements from the East Atlantic Ocean (Table 3) are comparable to Sargasso Sea measurements from August 2010 reported here, while the total Hg ranges for September 2008, 2009) are similar to the June 2008 Sargasso Sea average (0.81 pM) reported by Lamborg et al.\(^{48}\) Concentration differences among cruises are not explained by enhanced inputs from atmospheric deposition (precipitation was comparable among cruises\(^{37}\) or enhanced mixing with subsurface waters based on observed density profiles from the Bermuda Atlantic Time-Series region where cruises took place.\(^{46}\)

Total Hg concentrations measured across all cruises are characteristic of the range reported for the Atlantic basin as a whole and reflect variability in concentrations of water masses of different origins sampled over the various field seasons. Variability within cruises can be explained by the crossing of mesoscale vortices (<100 km radius) present within the Sargasso Sea. Further evidence is provided by Acoustic Doppler Current Profiler (ACDP) data. For example, data from September 2009 show several instances of rapid changes in current speed and direction. In one instance, the ship traveled from higher velocity waters (6–7 cm s\(^{-1}\), northerly flowing) to lower velocity waters (<1 cm s\(^{-1}\), easterly to southerly flowing) and then back again to the higher velocity waters over a timespan of 10 h. Water masses sampled therefore differ both between cruises and within individual cruises due to the sampling of different mesoscale features during transit.

**Variability in Percent Hg\(0\)/Total Hg in Seawater.** Across all cruises, we found a significantly higher proportion of filtered Hg as Hg\(0\) (\(^{2}\)Hg\(0\)) in offshore seawater with salinity >34.6 psu (15.8 ± 3.9%) compared to more freshwater influenced areas (7.8 ± 2.4%; <33.8 psu) (Figure S1). These findings imply that Hg\(0\) evasion will be proportionally higher in open ocean areas with the same Hg\(II\) concentrations and environmental conditions than those closer to the coast. For example, the lowest Hg\(0\) across the six cruises is found on the shelf in October 2009 when total Hg concentrations were similar to open ocean cruises (Table 2).

Differences in \(^{2}\)Hg\(0\) noted here are consistent with differences in dissolved organic carbon (DOC) content among coastal, shelf, and offshore water. In general, concentrations in coastal regions (110–150 μM) are higher than those offshore in the Gulf of Maine (55–90 μM) and in the vicinity of Bermuda (60–70 μM).\(^{49,50}\) While a large fraction of the organic carbon close to the shore is from allochthonous sources, DOC changes around Bermuda are mostly related to changes in primary productivity and seasonal water column mixing rather than freshwater inputs. Decreases in \(^{2}\)Hg\(0\) at lower salinities could be caused by enhanced stability of Hg\(II\) complexes with certain types of allochthonous DOC in shelf areas, effectively changing the size of the reducible Hg\(II\) pool.\(^{49,51}\) In higher salinity waters there appear to be higher concentrations of reactive Hg and reduced abundance of Hg-binding ligands.\(^{24,52}\) Reduced light penetration and photo-reduction in high DOC waters is also plausible because colored DOC is highly effective at attenuating light penetration in surface waters.\(^{53}\) Further elucidation of the types and composition of DOC–Hg complexes in coastal and offshore waters is needed to refine our understanding of the effect of DOC on Hg reduction kinetics.

**Controls on Hg\(0\) Distribution.** Table 4 shows results of linear and multiple regression analysis used to identify the relationships between continuously measured Hg\(0\) concentrations (\(n = 709\)) and environmental factors (temperature, salinity, wind speed, and in situ fluorescence). Because fluorescence was not calibrated against measurements of Chl a, it is a relative value and could only be included in the analysis of Hg\(0\) variability for individual cruises. Here we use fluorescence as a proxy for phytoplankton biomass,\(^{15}\) which in turn affects particle-associated scavenging of Hg\(0\) from surface waters and biological production of Hg\(0\).
Temperature and salinity are significant predictors of variability in Hg\textsuperscript{0} concentrations across all cruises and for individual cruises (Table 4), but the association with Hg\textsuperscript{2+} variability is both positive and negative across individual cruises. Temperature and salinity are positively associated with Hg\textsuperscript{0} concentrations when all Sargasso Sea cruises are combined but do not explain the majority of the variability in Hg\textsuperscript{0} concentrations ($R = 0.56$).

Mechanistically, higher seawater temperatures are expected to increase net reduction as well as enhance the diffusivity of Hg\textsuperscript{0}, increasing production from Hg\textsuperscript{2+} and evasion. Changes in salinity can also affect Hg\textsuperscript{2+} complexation with different ligands. Observed correlations are unlikely to reflect these mechanistic relationships given their mixed directions. Maximum temperature differences across the Sargasso Sea cruises were $< 4$ °C (Table 2), which we calculated would lead to $< 15\%$ change in evasion rates. Similarly, salinity differences across the Sargasso Sea cruises are $\sim 0.5$ psu and unlikely to result in major differences in the dominant Hg\textsuperscript{2+} complexes in seawater and associated reduction kinetics.\textsuperscript{55} Neither variable therefore accounts for the observed variability in Hg\textsuperscript{0} concentrations across all Sargasso Sea cruises.

Instead, given that temperature and salinity are also effective tracers of the differences in water masses sampled over the cruises, we conclude that the statistical relationships likely reflect different water masses sampled with variable Hg\textsuperscript{2+} available for reduction. This is further supported by the well-known occurrence of both cyclonic and anticyclonic vortices in the vicinity of Bermuda\textsuperscript{56} that are encountered and crossed during cruises, as indicated by ACDP data described above.

For the August 2008 shelf/slope cruise, when total Hg concentrations were elevated, there is no significant relationship with temperature in the linear regression analysis (Table 4). Variability in Hg\textsuperscript{0} concentrations for this cruise are likely driven by Hg\textsuperscript{2+} inputs from freshwater discharges (similar to total Hg) indicated by the negative association with salinity.

Wind speed both enhances the efficiency of air--sea Hg\textsuperscript{0} exchange by creating turbulence in surface waters (negative association with Hg\textsuperscript{0}) and facilitates mixing with deeper water that can provide additional Hg\textsuperscript{2+} substrate for reduction when near surface waters are depleted (positive association with Hg\textsuperscript{0}). We found a significant positive association between wind speed and Hg\textsuperscript{0} in multiple regression models for all cruises, for all Sargasso Sea cruises together, and when Sargasso Sea cruises are analyzed individually (with the exception of the September 2009 cruise where wind speed was not significant) (Table 4). These findings suggest that, across the sites studied, elevated winds are predominantly driving enhanced Hg\textsuperscript{0} and Hg\textsuperscript{2+} supply through mixing with deeper waters within the mixed layer rather than enhanced Hg\textsuperscript{0} loss through evasion (Table 4). This phenomenon is supported by high-resolution measurements of CO in the surface mixed layer near Bermuda that show variability in concentrations within the mixed layer.\textsuperscript{57} Wind speed is not a significant predictor in the multiple regression analyses of Hg\textsuperscript{0} concentrations for the shelf cruises, likely because freshwater inputs were more important for Hg\textsuperscript{0} supply than wind-driven mixing. High-resolution profiles of surface ocean Hg\textsuperscript{0} concentrations, in concert with measurement of unreactive gases, would further confirm the variable effects of wind on air--sea exchange and surface water mixing.

Fluorescence is negatively associated with Hg\textsuperscript{0} concentrations for individual Sargasso Sea cruises in the multiple regression analysis except for September 2008 when it is not significant. Although biotic reduction is known to occur in seawater,\textsuperscript{17,58} photochemical processes are much more rapid and tend to dominate overall reduction except under conditions of low light penetration and extremely high productivity.\textsuperscript{13} Increased productivity decreases light penetration in the surface ocean,\textsuperscript{53} diminishing photoreduction and associated Hg\textsuperscript{0} formation, and also decreases the pool available for reduction through the formation of stable Hg\textsuperscript{2+}--DOC complexes. Such processes likely account for the negative association between in situ fluorescence and Hg\textsuperscript{0} variability reported for the open ocean cruises.

For the August 2008 shelf cruise, the positive association between Hg\textsuperscript{0} variability and in situ fluorescence likely indirectly reflects the high Hg\textsuperscript{2+} nutrient and DOC signal from rivers that mixes with lower Hg\textsuperscript{2+}, nutrient and DOC from the Gulf rather than a causal association in the water column (Figure S3, Supporting Information). Accordingly, we see the expected negative correlation between fluorescence and Hg\textsuperscript{0} variability in the linear regression during the October 2009 shelf cruise when total Hg inputs from rivers are diminished (Table 4).

### Challenges for Estimating Annual Evasion Fluxes.

Evasion rates calculated here (Table 2) fall within the range of estimates from the past decade (Table 3) but are higher than those found during recent cruises in the East Atlantic.\textsuperscript{5,59} Accurately characterizing net evasion of Hg\textsuperscript{0} from marine systems on an annual basis is essential for understanding the time scales of anthropogenic Hg cycling through biologically relevant surface compartments\textsuperscript{2} and the pool of Hg\textsuperscript{2+} available for methylation.\textsuperscript{50} This requires extrapolating limited observational snapshots of Hg\textsuperscript{0} concentration and short-term flux measurements to larger spatial and temporal scales.

Previous studies have shown that variability in gas exchange model parametrization leads to a systematic difference in Hg\textsuperscript{0} evasion of $\sim 30\%$.\textsuperscript{16,37,38} To develop a complementary understanding of how daily variability in temperature, wind speed, seawater, and atmospheric Hg\textsuperscript{0} affect calculated evasion rates, we examined the daily standard deviation of 5-min resolution measurements collected here. We use the air--sea exchange model parametrization described in the Methods and do not compare differences across models, where uncertainty has already been characterized. On a daily basis, the impact of stochasticity in atmospheric and aquatic Hg\textsuperscript{0} and seawater temperature on estimated evasion are all less than the 30% difference in flux due to the choice of gas exchange model. The use of instantaneous (5-min resolution) wind speeds changes estimated daily Hg\textsuperscript{0} flux by 39--72%. In general, these results suggest that daily averaging of information on temperature and atmospheric and aqueous Hg\textsuperscript{0} concentrations is sufficient to estimate air--sea exchange within the bounds of our current mechanistic understanding of physical exchange processes.

Average evasion flux estimates across the six cruises vary by more than a factor of 3 (Table 2). This variability is primarily a function of differences in wind speed and seawater Hg\textsuperscript{2+} and to a lesser extent temperature. Using cruise-wide averages for temperature, wind speed, and aqueous Hg\textsuperscript{2+} results in a 4--22% difference in modeled evasion compared to fluxes estimated based on 1-h data for these model inputs (Table 2). These results again suggest that coarser resolution data provide reasonable estimates of fluxes across sampling periods. However, seasonal and interannual variability in evasion is large and greatly exceeds the variability introduced by short-term stochasticity in environmental parameters and Hg\textsuperscript{0} concentrations and uncertainty in gas exchange model parametrization.
Additional field data supporting enhancement of mechanistic models\textsuperscript{13} that simulate factors controlling seasonal and interannual variability in aqueous Hg\textsuperscript{0} redox kinetics are thus essential for refining estimates of global air–sea exchange. Our results indicate that high Hg\textsuperscript{0} concentrations (leading to high evasion) in near-coastal regions of the August 2008 shelf cruise are due to elevated total Hg inputs from rivers. This is similar to findings from other studies that have proposed shelf areas and closed seas have elevated evasion fluxes compared to the open ocean.\textsuperscript{6,29} However, the impact of spatially variable differences in seawater chemistry on Hg\textsuperscript{0} diffusivity and gas transfer velocity needs to be better accounted for in Hg\textsuperscript{0} evasion flux estimates. For example, Frew\textsuperscript{60} showed that the gas transfer velocity on the shelf and close to the New England coast decreased to \textasciitilde70\% and \textasciitilde20\%, respectively, of that in the open ocean due to differences in DOC content and surface film dynamics,\textsuperscript{60} which vary with seasonal dependent riverine inputs.\textsuperscript{51} Correcting for potential changes in gas transfer velocity using DOC concentrations for the August 2008 shelf cruise (using a linear relationship between salinity and DOC reported for the Gulf of Maine by Dai and Nelson\textsuperscript{69}) leads to 35–40\% decrease in the evasion flux shown in Table 2. Overall, better understanding of how differences in the composition of DOC and organic acids in marine waters effects the reducible pool of Hg\textsuperscript{0} and resulting evasion fluxes is needed.
