How does the GDQS work?

- The GDQS is a score ranging from 0 to 49 that is assigned to individuals based on their consumption of 25 food groups identified as globally important contributors to nutrient adequacy or risk of NCDs based on current nutrition science and epidemiological literature²,³ (Table 1). Point values are assigned to each food group based on three or four categories of amount of consumption defined in grams per day.

- The GDQS includes 16 ‘healthy’ food groups that receive increasing points for higher amounts of consumption, seven ‘unhealthy’ foods that receive increasing points for lower consumption, and two food groups – red meat and high-fat dairy – that receive increasing points up until specified consumed amounts, a tier at which no points are given (the scoring approach for red meat and high-fat dairy reflects that these food groups are important contributors to nutrient adequacy in LMICs, while also recognizing that high consumption of these foods is associated with NCD risk).

- GDQS scores ≥ 23 are associated with a low risk of both nutrient inadequacy and NCD risk, scores ≥ 15 and < 23 indicate moderate risk, and scores < 15 indicate high risk.

- The GDQS serves as a summary measure of overall diet quality with respect to both nutrient adequacy and diet-related NCD risk, while two GDQS sub-metrics – the GDQS+, composed of only the 16 healthy GDQS food groups, and the GDQS−, composed of the 9 GDQS food groups classified as unhealthy or unhealthy in excessive amounts – are useful for quantifying the contributions of healthy and unhealthy foods to overall diet quality in a given population.

- While the GDQS is assigned at the level of individuals, these sub-metrics are intended to be used to describe and compare diet quality at the group level.

What is the basis for the GDQS scoring approach?

We identified gram per day cutoffs for scoring the 25 GDQS food groups based primarily on their ability to produce a reason-
ably even distribution of trichotomous categories of consumed amounts in quantitative 24-hour recall and food-frequency questionnaire data from nonpregnant, nonlactating women in 10 sub-Saharan African countries, China, India, Mexico, and the USA. For high-fat dairy, we added a fourth scoring range to target very high consumption equivalent to roughly 3+ servings per day.

Variation in point values assigned to different consumption amounts was informed by the literature on contributions of different food groups to health, as well as secondary analysis in which we evaluated and statistically compared the performance of 32 metric variants in predicting outcomes related to nutrient adequacy and NCD risk in cross-sectional and cohort data from sub-Saharan Africa, China, India, Mexico, and the USA, and incrementally improved metric performance based on this analysis. In this analysis, we found that using three or four scoring categories per GDQS food group provided a predictive advantage over using two, so we adopted this approach despite the added burden for data collection that it implies.

Further details on design and operationalization of the GDQS are available online.6

“A single food-based metric can capture outcomes related to both nutrient adequacy and NCD risk in diverse settings”

Key takeaways from design and evaluation of the GDQS5

1. A single food-based metric can capture outcomes related to both nutrient adequacy and NCD risk in diverse settings, with performance comparable to that of existing metrics intended to capture only one of those domains.

2. Including both healthy-scoring and unhealthy-scoring food groups improved metric performance in predicting outcomes reflective of both nutrient adequacy and NCD risk.

Advantages of a food-based approach to measuring diet quality

A key feature of the GDQS is that it is entirely food-based. This facilitates use of the metric in limited-resource settings where data needed to calculate nutrient intakes (including local food composition data, recipes, and food preparation methods) are often inadequate or outdated. The GDQS’ food-based design is therefore highly conducive to cross-country comparisons of diet quality.

The GDQS’ ease of collection and analysis also allows rapid assessment of population diet quality, for obtaining time-relevant results. Furthermore, because the GDQS describes diet quality in terms of the contributions of healthy and unhealthy food groups, it provides simple and actionable data for improving population diet quality.

Developing and Validating a Food-Based Global Diet Quality Score

Table of contents

1. Developing and Validating a Food-Based Global Diet Quality Score

2. Including both healthy-scoring and unhealthy-scoring food groups improved metric performance in predicting outcomes reflective of both nutrient adequacy and NCD risk.

This finding is explained by the fact that consumption of healthy, nutrient-dense foods has been associated with better metabolic health in epidemiological studies (either directly, or by replacing unhealthy foods in the diet), while lower consumption of unhealthy food groups is also associated with better nutrition status. Consequentially, the GDQS does not differentiate food groups or point values when targeting either category of outcome (use of a single metric design also makes the GDQS simpler to use).

Unlikely in the MDD-W, unhealthy foods receive increasing points for lower consumption in the GDQS. This somewhat reduces correlations between the GDQS and nutrient intakes because unhealthy foods contain some nutrients. However, inclusion of these foods did not compromise associations with anthropometric and biochemical indicators of undernutrition in the analysis of data from sub-Saharan Africa and India.

Key takeaways from design and evaluation of the GDQS

1. A single food-based metric can capture outcomes related to both nutrient adequacy and NCD risk in diverse settings, with performance comparable to that of existing metrics intended to capture only one of those domains.

The naming of food group categories as ‘healthy,’ ‘unhealthy,’ and ‘unhealthy when consumed in excessive amounts’ provides a simple method for communicating how the foods in each food group contribute to an overall healthy diet, as reflected in the epidemiological literature and operationalized by the GDQS.

* Hard cheese should be converted to milk equivalents using a conversion factor of 6.1 when calculating total consumption of high-fat dairy for the purpose of assigning a GDQS consumption category. See4 for details on how to apply this conversion factor appropriately, according to the method used to collect the data.

As a simple metric of diet quality, the GDQS does not intend to capture information related to the consumption of fortified foods. Fortified foods should be classified in the food groups that correspond to the unfortified versions of those foods (e.g., orange juice fortified with calcium should be classified in the juice category; liquid oil fortified with vitamin A should be classified in the liquid oil category).
