Abstract

We develop and apply a new method for estimating the economic benefits of an environmental amenity. The method is based upon the notion of estimating the derived demand for a privately traded option to utilize an open access good. In particular, the demand for state fishing licenses is used to infer the benefits of recreational fishing. Using panel data on state fishing license sales and prices for the continental United States over a 15-year period, combined with data on substitute prices and demographic variables, a license demand function is estimated with instrumental variable procedures to allow for the potential endogeneity of administered prices. The econometric results lead to estimates of the benefits of a fishing

* Financial support of this work was provided by Resources for the Future, the U.S. Environmental Protection Agency, and the Dean's Research Fund, John F. Kennedy School of Government. The analysis benefitted from discussions with Andrew Metrick, Richard Newell, and Kerry Smith, and comments from participants at seminars at the National Bureau of Economic Research and Harvard University, and very helpful comments from two anonymous referees. The data set, which builds upon previous work by Wolf (1988), was assembled with the help of a series of research assistants, including: Rod Bender, Nancy Bilica, Alisha Bloom, Diane Cherry, Peter Condon, Andrew Hoffman, and Michael Susanto. The authors alone are responsible for any errors.

license, and subsequently to the expected benefits of a recreational fishing day. In contrast with previous studies, which have utilized travel cost or hypothetical market methods, our approach provides estimates that are directly comparable across geographic areas. Our findings show substantial variation in the value of a recreational fishing day across geographic areas in the United States. This suggests that current practice of using benefits estimates from one part of the country in national or regional analyses may lead to substantial bias in benefits estimates.

Key words: revealed-preference valuation, environmental benefits, recreational fishing day

JEL Classification: Q26, Q21, Q22, H41

1. Introduction

When considering regulatory actions for a number of disparate environmental and natural resource problems, policy makers may wish to have estimates of the economic value of a day of recreational fishing. Such values can be used to measure the recreational benefits of proposed regulatory or other policy actions. In the past, such estimates have been used in economic impact analyses of: new dams and reservoirs, improvements in water quality, cleanups of abandoned hazardous waste sites, and reductions in the magnitude of global climate change. Virtually all of these estimates have drawn on one of two methods: contingent valuation, a direct survey approach employing hypothetical constructed markets; or travel-cost, an indirect market-based method. The use of the first of these approaches has generated considerable controversy within economics;¹ and both approaches require large quantities of geographically specific data. The majority of analyses by government agencies—including benefits estimation for Regulatory Impact Analyses—do not employ new site-specific or policy-specific studies of the value of a recreational fishing day. Rather, these analyses typically employ “benefit transfer methods,” whereby estimates from a previous study are applied—sometimes with modifications—to a new and different policy scenario (Desvousges et al. 1998).

In this context, it may be of interest to have an additional set of estimates—based upon a conceptually distinct, revealed-preference approach—of the economic benefits of a recreational fishing-day (Stavins 1992). Our methodology differs from previous studies in two important respects. First, we estimate willingness-to-pay for a recreational fishing day from observed behavior regarding the purchase of fishing licenses, rather than observed behavior regarding travel to sites or stated preferences regarding those sites. Second, the two existing approaches² use detailed

1 For an overview of the controversy (see Diamond and Hausman 1994; Hanemann 1994; Portney 1994).

2 Other direct, revealed-preference methods that have been used for examining other environmental amenities and that require detailed micro-data—hedonic property and wage models—have not

micro-data (of observations of opportunity costs of travel or respondents' explicit estimates of willingness-to-pay) to develop benefit estimates specific to particular bodies of water and particular changes in water quality. This is both their advantage and disadvantage. In contrast, the approach developed in this paper uses aggregate data at the state level to derive estimates—in a national modeling framework—of state averages of recreational benefits.³ As a result, our state estimates are directly comparable among one another, allowing inferences to be made about relative recreational benefits across geographic areas with more confidence than is possible based on previously available methods.

In Part 2 of the paper, we outline the theoretical framework underlying our estimation strategy. In Part 3, we describe our data, and in Part 4, we describe the econometric analysis, including the results from generalized least squares (GLS) and instrumental variables (IV) regressions. In Part 5, we use the econometric results from the IV equations to derive estimates of average expected recreational fishing day values, and we compare these estimates with results from previous studies. In Part 6, we conclude.

2. Overview of Method

Throughout the United States, a state fishing license is required for recreational fishing on any and all bodies of water, with the exception of privately owned ponds. Thus, apart from the possibility of illegal fishing activity, to which we return below, a license is a necessary condition for deriving benefits from a day of recreational fishing. Likewise, apart from the relatively rare urbanite who may enjoy displaying to others an (unused) fishing license, experiencing some fishing days is a necessary prerequisite for deriving benefits from owning a fishing license.⁴

Building upon the household production approach to consumer behavior (Becker 1965), Bockstael and McConnell (1983) identified the conditions under which empirical knowledge of the demand function for a private, market good could be used to infer the benefits derived from a related public good. In a simple model,⁵ let X be the number of fishing days experienced, L a fishing license, and Z a composite of other goods and services. If utility is defined by the function,

been applied to estimating the value of recreational fishing days (Freeman 2003). In principle, a sport fishing demand function could also be estimated in some cases by drawing on data from pay-for-use facilities, such as private, managed trout ponds, where users are charged for access or use (Vaughan and Russell 1982).

- 3 Seneca and Davis (1976), in an analysis of the factors affecting participation in recreational activities, carried out a county-level, cross-sectional econometric analysis of the factors affecting fishing license sales in West Virginia in 1970. Because there was no variation in license prices in the cross section, price could not be included as an explanatory variable.
- 4 We return later to the possibility that the license provides its owner with the *option* to go fishing, and thereby that simply *expecting* to go fishing is all that is required for a person to derive benefits from owning a license.
- 5 For a detailed theory of the utilization of recreational fisheries (see Anderson 1993).

$$U = U(X, L, Z) \quad (1)$$

then the above situation can be represented by the following pair of marginal utility relationships:

$$\frac{\partial U(X, 0, Z)}{\partial X} = 0 \quad (2)$$

$$\frac{\partial U(0, L, Z)}{\partial L} = 0 \quad (3)$$

defining what McConnell (1992) termed “joint weak complementarity.” Thus, we can employ information about peoples’ revealed valuation of fishing licenses, measured by the appropriate area under the respective demand functions, to draw inferences regarding their revealed valuation of (expected) recreational fishing days (Smith 1991).

The first step is to estimate econometrically a set of demand functions for state annual recreational fishing licenses. By measuring the appropriate area under the (state-specific) inverse demand function, we can estimate the average benefits per capita of fishing licenses. Further manipulation leads to an estimate of the average benefits of fishing licenses *per license* (again, specific to states and years). From this we derive a revealed-preference estimate of the expected value of a recreational fishing day. This value can be compared with estimates derived in previous studies by contingent valuation or travel cost methods.

3. Data

Recreational fishing licenses are sold by all 50 states. In all cases, prices are administratively set by state governments, and licenses are sold without limit.⁶ This study focuses on a panel of licenses sold in 48 states⁷ over a 15-year period (1975–1989). We aggregated the numerous types of fishing licenses that exist into 10 categories. All states offered both resident and nonresident licenses, the former at lower prices. Resident annual licenses were by far the most popular type, with sales of more than 257 million over the 15-year sample period, representing about two-thirds of all licenses sold (Table 1).⁸ Second in numerical importance were resident “combination licenses” that allow for both hunting and fishing during a given year.

6 Because fishing licenses are sold without limit, they are not used to limit fishing activity or to correct environmental externalities. Rather they are used primarily as a revenue generating source for states.

7 Hawaii is excluded from the analysis because the structure of license demand does not match the rest of the United States, and Tennessee is excluded because it does not sell a fishing license *per se*, but a “Sportsman License,” which can be used for both hunting and fishing.

8 Two states—Montana and Wyoming—required the purchase of a “conservation stamp” in addition to a fishing license. The cost of the stamp was added to the price of a license.

Table 1. Major Categories of Recreational Fishing Licenses Continental United States, 1975–1989			
Total License Sales ($T = 15$ Years, $N = 48$ States)			
License Type	Number ^a	Share (%)	Total Number of Observations (NT)
Resident Annual	257,054,000	67.6	720
Resident Combination ^b	52,690,000	13.9	481
Resident Short-Term 1 ^c	9,661,000	2.5	203
Resident Short-Term 2 ^d	349,000	0.1	71
Resident Short-Term 3 ^e	986,000	0.3	29
Nonresident Annual	20,059,000	5.3	709
Nonresident Combination	795,000	0.2	118
Nonresident Short-Term 1	17,022,000	4.5	378
Nonresident Short-Term 2	15,034,000	4.0	422
Nonresident Short-Term 3	6,374,000	1.7	203
All License Categories	380,024,000	100	3,305

^a Rounded to the nearest 1,000.
^b "Combination" licenses cover both fishing and hunting on an annual basis.
^c "Short-Term Type 1" licenses are temporary fishing licenses, ranging in length from 1 to 3 days.
^d "Short-Term Type 2" licenses are temporary fishing licenses, ranging in length from 4 to 9 days.
^e "Short-Term Type 3" licenses are temporary fishing licenses, ranging in length from 10 to 15 days.

Various duration short-term fishing licenses were also available to residents in many states; these allowed for as little as a single day or as much as two weeks of fishing, but—in total—made up only 3 percent of all resident fishing license sales. In contrast, nonresident license sales were much more heavily weighted toward short-term permits. In fact, about 65 percent of all nonresident fishing license sales during the sample period were of short-term licenses (Table 1).

There was substantial variation in aggregate and per capita sales of the various types of licenses. The variation was greatest across states, but was also significant within states over time. For example, in the final year of the sample, resident annual license sales ranged from about one percent to over 25 percent of state population. There was also considerable variation in (real) license prices across states and over time. In the case of resident annual licenses, the range in the sample was from a minimum of \$3.79 to a maximum of \$32.80⁹ (Table 2). In the final year of the sample, the range was from \$7.63 (Minnesota) to \$26.73 (Colorado). The variation was even greater for some of the other license categories. For example, in 1989, the minimum price of a nonresident annual license was \$16.66 (South Dakota) and the maximum was \$69.44 (California).

⁹ These and all other monetary amounts in this paper are expressed in year 2000 dollars.

In addition to the license price and quantity information, data were assembled on various demographic, political, and environmental variables that were thought to be relevant to license demand or necessary for establishing the links between license demand and participants' expected benefits of a recreational fishing day. These data are summarized in Table 2 and discussed in the next section.¹⁰

4. Econometric Analysis of License Demand

Since license prices are set administratively by states, and licenses are sold without limit, the quantity sold at various prices traces out a demand function if the administratively set prices are exogenously determined and if any relevant variables that are omitted are uncorrelated with the license price.¹¹ The first set of variables—in addition to the license price itself—that would seem to be relevant are the prices of major substitutes. In this analysis we focus on the demand for resident annual fishing licenses, and therefore the relevant substitute prices include the price of resident short-term fishing licenses, the price of resident combination fishing and hunting licenses, and the price of nonresident licenses in adjacent states.¹²

Presumably, the characteristics of demanders are also relevant, and we therefore included the following demographic variables in the resident license demand estimation: median family income; mean years of education; and the share of the population living in urban areas. Finally, the nature of available recreational fishing resources in states should affect demand for state fishing licenses. We dealt with this in two ways. First, we included a variable that measures acres of “fishable waters” per state,¹³ but this treats all fishing resources as being homogeneous in terms of the experiences they offer. Clearly, this is not correct. An acre of pristine, high-quality Colorado mountain stream is not equivalent to an acre of Ohio reservoir. The omitted variable—quality of fishing waters—is likely to be important and may be correlated with license price, hence causing biased estimates of demand

10 A detailed table of fishing license prices by year and state is available from the authors upon request.

11 Under these conditions, the observed price-quantity combinations are the intersections of infinitely elastic license supply functions (one for each price) and an assumed downward-sloping license demand function. A graph of the change in quantity of fishing licenses demanded against the change in license prices shows a negative correlation resembling a downward sloping demand curve. This is the pattern that would be expected if prices were administratively set. This data pattern is not surprising because revenue generation, rather than regulation of environmental externalities, is the primary goal of selling fishing licenses.

12 A problem arises in specifying which state licenses are relevant as substitutes. We constructed a variable that is a weighted average of prices of specified types of nonresident licenses in adjacent states and Canadian provinces.

13 Note that this variable varies not only across states, but also over time, reflecting both development of new reservoirs and changes in water quality.

elasticity. The problem presented by such unobserved quality is not insurmountable, because although quality variation is dramatic across states, quality variation within states over time is trivial by comparison. Hence, we can model this unobserved factor as a fixed effect.¹⁴

This leaves one concern regarding the possibility of inferring a true demand relationship from econometric estimates: is it supply, demand, or some combination of the two that is being observed? In other words, are price and quantity simultaneously determined, or are prices *exogenously* set by states? A reasonable first approximation is that the administered prices are set exogenously by state officials, and so we begin with simple GLS estimates. But it is not difficult to posit theories of administered prices that support the notion that these prices are endogenous. Hence, we follow the GLS estimates with a set of specifications in which we treat the license price as endogenous, and estimate the relationships with IV methods.

4.1. Generalized Least Squares (GLS) Estimation

Resident annual licenses comprise approximately two-thirds of all fishing licenses sold in the United States.¹⁵ For resident license demand, the dependent variable was expressed as sales per capita.¹⁶ The variance in license sales per capita is likely to be smaller in states with larger populations, thus violating the homoskedasticity assumption of an ordinary least squares (OLS) estimator. To correct for this, we employ a GLS procedure that weights each observation by the square root of the state's population (Bowes and Loomis 1980). In addition, fixed effects were employed to control for constant differences among states in the quantity and quality of their recreational fishing resources. Thus, the demand for resident annual licenses is estimated as:

$$\frac{Q_{it}}{N_{it}} = f(P_{it}, P_{it}^{S1}, D_{it}^{S1}, P_{it}^{S2}, D_{it}^{S2}, P_{it}^{S3}, D_{it}^{S3}, P_{it}^{NR}, F_{it}, U_{it}, E_{it}, Y_{it}, D_i, D_t, \varepsilon_{it}, \beta) \quad (4)$$

where Q_{it} = quantity of sales of resident annual license in state i in year t ;

N_{it} = population of state i in year t ;

P_{it} = price of resident annual license in state i in year t ;

14 If preferences for fishing opportunities differ significantly across states, the parameters of the demand functions should likewise differ. The data do not allow us to estimate separate demand functions for each state, so we allow differences in preferences to be captured by fixed effects and by demographic control variables. Our approach assumes that each individual within a state has the same willingness to pay. However, in the absence of individual data, we cannot directly address within-state heterogeneity.

15 To whatever degree the holders of annual licenses have greater or lesser fishing-day valuations than holders of other categories of fishing licenses, the eventual results will tend to over or under-estimate average state valuations.

16 These equations were also estimated with sales as the dependent variable and state population as an independent variable; the estimated parameters on population were not significantly different from 1.0 (in the primitive equations).

- P_{it}^{S1} = price of short-term, type 1 (1–3 day) resident license in state i in year t ;
 D_{it}^{S1} = dummy variable which equals unity if a short-term, type 1 resident license is not offered in state i in year t , and otherwise equals zero;
 P_{it}^{S2} = price of short-term, type 2 (4–9 day) resident license in state i in year t ;
 D_{it}^{S2} = dummy variable which equals unity if a short-term, type 2 resident license is not offered in state i in year t , and otherwise equals zero;
 P_{it}^{S3} = price of short-term, type 3 (10–15 days) resident license in state i in year t ;
 D_{it}^{S3} = dummy variable which equals unity if a short-term, type 3 resident license is not offered in state i in year t , and otherwise equals zero;
 P_{it}^{NR} = average price of adjacent state nonresident annual licenses for state i in year t ;
 F_{it} = area of fishable waters (acres) in state i in year t ;
 U_{it} = share of population living in urban areas in state i in year t ;
 E_{it} = mean years of education of population in state i in year t ;
 Y_{it} = median family income in state i in year t ;
 D_i = state fixed effects;
 D_t = annual fixed effects;
 ε_{it} = an independent, but not necessarily homoskedastic error term;
 β = parameters to be estimated.

The results of estimating the fixed effects model of demand for resident annual fishing license are reported in Table 3.¹⁷ We report two specifications: one includes the prices of all relevant substitutes as explanatory variables,¹⁸ and the other includes only the price of short-term Type 1 licenses plus dummy variables for each year.

In general, estimated own price effects were negative and statistically significant, and substitute price effects were positive, as expected.¹⁹ The parsimonious

17 The reported results are for a semi-log functional form. The demand function was also estimated using linear and log-log functional forms. We report the semi-log results because we believe the demand function is unlikely to be linear, as that would imply that at a zero price there is a finite demand, and because the semi-log results consistently had a better fit than the log-log results. Of course, a more fully specified, structural model of demand would—in principle—be preferred, but it would be necessary to make other assumptions of questionable plausibility. We choose instead to estimate several demand specifications, and trace out the range of likely results with robustness tests. A full set of results for all functional forms is available from the authors upon request.

18 Not all states offer all categories of substitute (short-term) licenses during all time periods. In a sense, the “prices” of these non-existent licenses are infinite. The various specifications allow for the effect of some type of license not being available through the inclusion of dummy variables, D_{it} , where $(1-D_{it})$ is interacted with the respective license price, so that for each observation either a substitute price effect or a lack-of-substitute effect is estimated. In theory, both should be positive, which they consistently were.

19 But when the full menu of substitute prices was included, some of the respective parameters were insignificant and negative. The prices of nonresident licenses in neighboring states performed particularly poorly. This could be because the simple arithmetic average of neighboring state prices does not correctly capture the role that neighboring state fishing opportunities play in the demand for resident annual licenses. If sufficient data were available, it would be preferable to allow the econometrics to determine the appropriate weighting of the neighboring state prices.

specification that included only short-term Type 1 resident licenses as substitutes consistently yielded positive and statistically significant coefficients (for all functional forms).²⁰ The attempt to capture (partially) resource-quality effects with the fishable waters variable met with limited success. Presumably, much of the variation in the quality of fishing resources across states was picked up by the fixed effects. Finally, the demographic variables seem to have had some effect on fishing license demand. In several specifications, income was positive and statistically significant. In other specifications, years of education was negative and significant. Goodness-of-fit statistics were reasonably good for these fixed-effects models, with R^2 on the order of 0.15–0.23; not surprisingly, the complete models—including the fixed effects—explain a greater share of the observed variance.²¹

4.2. Potential Problems

These results raise two major concerns regarding the effect of illegal fishing activity and the possibility of endogeneity of license prices. Since the purpose of econometrically estimating fishing license demand is to derive implied valuations of expected recreational fishing days, it is necessary to consider the implications of illegal fishing, that is, fishing without a license.²² This, by itself, need not be a problem given the approach that is taken below to derive valuation from license demand, but it can lead to bias in the econometric estimates.

A theoretically desirable way of treating illegal fishing in the license demand equation would be to allow for this particular substitute activity. Hence, we would want to include as an explanatory variable the “price” of illegal fishing, which may be thought of as the magnitude of fines multiplied by the probability of being fined. Unfortunately, these fines are typically set by courts, not by statute or regulation, and data even for proxies of the probability of being fined (enforcement levels) are rarely available.²³ Although it is reasonable to assume that the true “price of illegal fishing” is positively correlated with the demand for

20 The latter specification includes dummy variables for each year in the sample. On average, nominal license prices changed only 2.5 times per state over the 15-year sample period. Therefore, much (but not all) of the intertemporal variation in prices consists of gradually declining *real* prices. If, at the same time, sales were drifting upward, this would yield a negative correlation, but not one due to price-quantity demand effects. The yearly dummy variables were included to examine this potential problem. However, their inclusion did not materially affect the results, and so it appears unlikely that the observed negative price elasticities were due to such spurious correlation.

21 A Hausman specification test consistently rejected the hypothesis that state-level variation could be adequately modeled as a random effect.

22 If we were concerned with the demand for fishing licenses per se, then illegal fishing would not be a problem for the econometrics; indeed, in that case it is important to exclude illegal fishing, as the data implicitly do. Why might one be interested in license demand in and of itself? One reason is that such an analysis can provide the relevant elasticities for examining revenue and other effects of fishing license taxes of various forms.

23 To whatever degree these factors and their effects vary across states but are constant over time, they are picked up by the state fixed effects.

Table 2. Recreational Fishing Licenses, 48 States, 1975–1989 Descriptive Statistics

Variable	Mean ^a	Standard Deviation	Minimum	Maximum	Number of Observations
Quantity of Resident Annual Licenses per State	357,019	362,301	10,925	2,293,671	720
Quantity Per Capita of Resident Annual Licenses	0.091	0.050	0.010	0.249	720
Price of Resident Annual Licenses	\$14.89 ^b	3.48	\$3.79	\$32.80	720

fishing licenses, it is much less clear how it is correlated with license prices, if at all. Hence, omitting this variable may not seriously bias the elasticity estimates.²⁴

There is also the possibility that license prices, administratively set by governments, are endogenous, that is, that causality runs not only from price to quantity, but vice-versa. How could this be the case? One potential source of such a causal linkage would be state budgets. States might seek to set license prices at levels that cover annual budgets of fish and game services, assumed to be more or less fixed over time (Whitehead 1983; Walsh 1986). In the time series for a single state, this could yield a negative correlation between quantity of license sales and administered price (recognizing that this assumes that states can predict sales).

Another potential explanation for a spurious, negative price-quantity correlation is associated with persons sorting themselves for residence among states. People with strong preferences for fishing may be expected to exert political pressure to keep license prices low. If people with strong preferences for fishing move to relatively good fishing states (or develop preferences for fishing as a result of having been born and raised in such a state), then states with large quantities of license sales could tend to have relatively low prices, suggesting a source of spurious, negative cross-sectional correlation. We allow for price endogeneity by identifying a set of instruments for license price, and by using instrumental variables in what is essentially a reduced form approach.²⁵

4.3. Instrumental Variable (IV) Estimation

To address possible price endogeneity, we wanted an instrument or set of instruments that would be correlated with resident annual license prices, but uncorrelated with unobservable determinants of license sales (for example, preferences for fishable waters). That is, we wanted instruments that are exogenous to the demand for fishing licenses. Preferences for fishable waters can affect overall expenditures on water quality improvements, but such expenditures can be funded through user fees (fishing license sales) or through general tax revenues. The relative degree to which these two sources of revenue are utilized is determined largely by bureaucratic and political proclivities. Thus, it would be desirable to have instruments that represent states' (possibly changing) proclivities to employ user fees as opposed to taxes and regulations. These proclivities might be correlated with administrative prices of fishing licenses, but are less likely to be correlated with the quantity of fishing licenses sold. The set of instruments used in this analysis were: cigarette taxes (cents per package); motor fuels taxes (cents per gallon); general sales taxes (percent); and state expenditures (millions of dollars).

24 A more serious problem arises, however, if illegal fishing increases when license prices increase, perhaps as a form of protest. If this is the case, then demand responsiveness will be overestimated and the benefits of licenses will be underestimated.

25 A third potential problem with the fixed effects estimation results presented in the previous section is that the fixed effects model allows the intercept to vary, but other demand parameters are constrained to be equal across states. The data do not permit estimation of separate demand functions for each state.

The IV regression results are reported for the parsimonious specification in Table 3.²⁶ The results are robust to different specifications, including changes in the list of substitute prices and changes in the demographic variables. The parameters on the price and fishable waters variables are all of the logical sign and statistically significant, although several are quite small in magnitude. The demographic variable parameters are all of the expected sign, although some are not statistically different from zero. The own-price elasticity of demand is consistently greater (in absolute value) in the IV estimates than in the GLS estimates.²⁷

5. Estimating The Value of a Recreational Fishing Day

Three steps were required to derive the (state and year specific) average expected value of a recreational fishing day from the econometrically estimated demand functions for fishing licenses: derive average benefits of fishing licenses per capita from an estimated demand function; calculate average benefits per licensee; and estimate average expected value of a recreational fishing day.

5.1. Estimating Average Benefits of Owning Fishing Licenses from the Demand Function

To derive the average benefits of a fishing license (in per capita terms), we begin with an equation for which the parameters have been estimated econometrically. From our econometric estimates, we obtain both point estimates and uncertainty estimates (in the form of the variance-covariance matrix) on the key parameters of the demand for fishing licenses. We begin by using the point estimates to derive our measure of benefits and then use the uncertainty estimates to calculate 90% confidence intervals for those benefit measures.

To estimate the value of a recreational fishing day, we begin by estimating the total benefits derived from fishing licences as measured by the area under the inverse demand curve. To calculate this area, we first set all variables—with the exception of the (annual resident) license price and the dependent variable (sales per capita)—equal to their actual values for a given state and year. Also, we set all parameters at

26 The instruments are good predictors of fishing license prices. The F-statistic for the first stage regression is 10.98, and the instruments are jointly significant at the one-percent level.

27 This suggests that whatever endogeneity underlies these results, it is not due to either of the linkages posited above, both of which suggested a negative bias for the GLS results. One test of the potential endogeneity of the price variable regresses the license price on the instrumental variables and then includes the predicted price from this first-stage regression as an explanatory variable (in addition to the licence price itself) in the quantity regression. If the coefficient on the predicted price variable is statistically significant, then it is drawing variance from the error term that would otherwise be attributed to the price variable. This would be what we would expect if the price variable was endogenous. We found that the predicted price variable was marginally significant (at the 10% level) when included in the quantity regression. This provides some evidence that price is endogenous. As a result, we use the IV regressions in our benefits estimation.

their econometrically estimated values. The inverted form of the resulting equation (that is, the inverse demand function) is then integrated between the actual per capita demand (sales per capita) and zero, yielding an estimate of the (revealed) benefits per capita of fishing licenses for each state and year. Multiplying by the state's population produces an estimate of the total benefits of licenses; and dividing this by license sales yields an estimate of the average revealed benefits of owning a fishing license *per licensee*:

$$B_L = \left[\int_c^{q_{it}} f(\hat{\alpha}_{it}, \hat{\beta}_0, q) dq \right] \cdot \frac{N}{Q} \quad (5)$$

where $f(\cdot)$ = inverse demand function;

q_{it} = per capita sales of resident annual licenses in state i in year t ;

c = appropriate cutoff (zero for linear and semi-log specifications of the demand curve);

α_{it} = the fitted value from setting all variables—other than (annual resident) license price and the dependent variable—equal to their actual values for state i in year t , and all parameters, including the relevant fixed, state effect, at their econometrically estimated values;

β_0 = the estimated own-price elasticity of demand; and

B_L = average benefits of owning a fishing license (per licensee).

These average benefits of a recreational fishing license can be combined with information on the expected number of fishing days to derive a benefit estimate for a recreational fishing day. This is the focus of the next section.

5.2. Estimating the Expected Value of a Recreational Fishing Day

Since an annual fishing license is essentially an option to purchase (through direct expenditures plus opportunity costs of time) some number of days of recreational fishing experience (up to the total number of days in the season), it would seem that the stochastic relationship between a fishing license and the experiences it can facilitate would bring forth an important component of “option value.” After all, no one knows with certainty how many days they will be able to go fishing during a season. Two conditions, however, essentially undue the option value, and make it possible to infer user value directly. First, annual license sales continue throughout the season, up until the very last day. Hence, there is no necessity to purchase a license *before* the time of one's first expedition. Second, numerous short-term licenses (substitutes) are always available.²⁸

28 It is also true that an annual fishing license could offer option value for someone who decided he wanted to go fishing (for the first time in a season) in the middle of the night, when local outlets for purchasing a short-term license are closed. But this does not represent an important class of exceptions.

Thus, if short-term licenses did not exist *and* if there were an early deadline for purchasing annual licenses, then it could be argued that any valuation linked with licenses would include both user and option value. In the absence of those conditions, however, it seems more reasonable to assume that the benefits of a fishing license are linked with expected use value. If we assume that consumers are risk neutral in regard to their fishing license purchases and that the duration of a fishing season is short enough that discounting is not a significant issue, then we can derive the approximate conditional value of an expected fishing day in a very direct manner from the license demand evidence. First, we can say that:

$$B_L = E[B_{FD}|B_{FD} > 0] \bullet pr[B_{FD} > 0] \bullet S \quad (6)$$

where B_{FD} is the benefit (value) of a recreational fishing day; and S is the number of days in the season. The probability that the benefits are positive will be equivalent to the expected number of days of recreational fishing experienced, $E[d]$, divided by the length in days of the season, S . Therefore, we have the following:

$$E[B_{FD}|B_{FD} > 0] = \left[\frac{B_L}{E[d]} \right] \quad (7)$$

Thus, we can approximate the conditional value of an expected recreational fishing day by dividing the revealed valuation of an annual license by the expected number of fishing days. This is subject to four caveats. First, these relationships assume risk neutrality. If license purchasers are risk averse, then we will over-estimate the daily valuation. This seems, however, to be a second-order problem. Second, we have ignored discounting, but it is unlikely to amount to a significant error (relative to econometric and other sources of error), considering the length of the fishing season. Third, this assumes independence of the valuation of each day, but if there is declining marginal valuation of fishing days by license holders and serial correlation among days of participation, then such independence does not hold. Fourth, depending upon the nature of unobserved heterogeneity among licensees within states, the aggregation may not produce the correct weighted average.

This takes us to the point of estimating the average expected number of fishing days per licensee per state per year, $E[d_{it}]$. Various approaches to this problem exist, but a reasonable approximation is simply to use the actual numbers, which are periodically compiled at the state level by the U.S. Fish and Wildlife Service (FWS).²⁹ This may impart a slight upward bias to the final results, since the FWS numbers refer to all (resident) participants, not only annual license holders. Some of these are short-term license holders, who likely go fishing less frequently.

29 As reported in U.S. Fish and Wildlife Service (1975, 1980, 1985, and 1991), the surveys provide annual estimates of state-level total days of recreational fishing (separately by residents and nonresidents) and the number of participants. The estimates from those five years were interpolated to provide a set of annual estimates for the period, 1975–1989. The U.S. average over this time period is about 20 days per year for residents and 10 days per year for nonresidents.

But the overwhelming majority of licenses sold are annual licenses, implying that this problem will not be important. A final point concerns uncertainty estimates. We use Monte Carlo procedures to simulate confidence intervals for the benefits of a recreational fishing day.

The results from this analysis are summarized in Table 4, which provides benefit estimates derived with the semi-log IV regression, averaged over the sample period. Our results provide evidence of substantial heterogeneity among states in the expected value of a recreational fishing day. The mountain states plus Alaska, Arkansas, and Minnesota exhibit valuations that are 10 or even 20 times the magnitude of the estimates for the lowest value states, such as Delaware, Massachusetts, and Rhode Island. This should not be surprising, and any absence of such dramatic contrasts in previous studies might even be a source of concern. Our results reflect considerable uncertainty, however. The 90% confidence intervals are typically large, both in absolute terms and relative to the estimated benefits of recreational fishing.

5.3. Comparisons of National Revealed Preference Estimates with Site-Specific Estimates

The primary innovation in this study is to use revealed preference methods to derive the value of a recreational fishing day from market data on a national scale. Other methods, both revealed and stated preference, rely on detailed site-specific data. While these studies are often well-constructed and can provide good estimates of the value of a recreational fishing day for a specific site, the applicability of these benefit estimates to changes at other sites is questionable. To illustrate the potential problems, we contrast our estimates with previous estimates of the value of a recreational fishing day in Table 5, drawing upon a number of earlier studies that used either contingent valuation or travel-cost methods (but typically do not report confidence bounds).³⁰

Our results appear to be generally lower than previous estimates.³¹ It should be noted, however, that in 10 out of 13 cases, the 90% confidence interval of our valuations include the point estimates of respective previous valuations. Likewise, in four out of the seven instances in which previous studies provided confidence bounds, our 90% confidence limits on valuations fall within the respective 90% confidence limits from the previous analyses.

Perhaps more important than the absolute numbers, however, are the relative estimates of the benefits of recreational fishing across states. No matter which specification we use, the findings imply that fishing in states such as Colorado,

30 We only consider states in Table 5 for which previous studies exist of the time period employed in our analysis and for which our results yield estimates that are statistically different from zero.

31 An exception is that our estimate is higher than the only contingent valuation (CV) study in the comparison group. This is consistent with findings from Loomis et al. (2000), who use a similar method with hunting licenses.

Table 4. Estimates of the Value of a Freshwater Recreational Fishing Day (1975–1989 averages, 2000\$, Based on Weighted Semi-Log Instrumental Variables Regressions)

	Estimated Value	90% Confidence Interval from Monte Carlo Analysis	
Alabama	28.86	8.10	53.39
Alaska	1,078.53	247.74	2,422.94

Wisconsin	50.96	12.01	112.74
Wyoming	3,793.74	854.97	8,731.08

Minnesota, Oregon, and Wisconsin, for example, conveys much greater recreational value than fishing in many other areas.

These differences in relative benefit estimates reinforce concerns about the validity of so-called “benefit transfer” methods, which extrapolate findings from site-specific studies to other specific sites or to a national scale. While concern about these methods is not new (U.S. Environmental Protection Agency 2000), the lack of viable national alternatives on which to base benefit estimates has increased reliance on benefit transfer methods. This study provides a supplemental approach, and the results indicate that a policy maker who were to extrapolate findings from site-specific studies of fishing in Oregon, for example, to other parts of the country would be employing a highly biased estimate.

Throughout the above discussion, we emphasized factors that could alter our findings. First, if there is significant option value of licenses, the actual (use value) benefits of recreational fishing would be even less than estimated here. Second, if illegal fishing increases when license prices increase, demand responsiveness will be overestimated, implying that the benefits of licenses are underestimated. Third, to the extent that other license holders may have systematically different valuations than annual license holders, our estimates will be affected. Fourth, our calculation of the expected number of fishing days relies upon FWS statistics, which may contain errors of their own.

6. Conclusions

Economic analyses of many proposed environmental and resource regulations rely critically on accurate estimates of recreational benefits. To date, the source of most information on the value of a recreational fishing day has come from site-specific methods. The data requirements for site-specific contingent valuation and travel cost methods are severe, and hence the expense of carrying out such analyses is a major impediment to their use. Furthermore, there is ongoing controversy surrounding the use of the CV and other hypothetical market methods for environmental benefits estimation. For these reasons, government agencies such as the U.S. Environmental Protection Agency rarely carry out original analyses, typically relying instead on “benefit transfers” from other studies. But the validity of transferring values derived for one specific site to other sites is often equally suspect. Given these realities, it is of considerable value to have access to a conceptually distinct method of estimating environmental values that is based upon a revealed-preference, econometric framework. As such, the method developed here holds promise.

Our numerical estimates of recreational fishing-day values suggest great variation across geographic areas. Since previous studies have been of single sites or single states, there was inevitably some question as to whether and to what degree any observed variations were due to real differences in values, as opposed to differences among respective models. Although our approach may suffer from being a macro-oriented approach—in contrast with survey methods and travel-cost
