This manuscript was compiled on August 31, 2020

The drift diffusion model (DDM) is a model of sequential sampling with diffusion signals, where the decision maker accumulates evidence until the process hits either an upper or lower stopping boundary, and then stops and chooses the alternative that corresponds to that boundary. In perceptual tasks the drift of the process is related to which choice is objectively correct, whereas in consumption tasks the drift is related to the relative appeal of the alternatives. The simplest version of the DDM assumes that the stopping boundaries are constant over time. More recently a number of papers have used non-constant boundaries to better fit the data. This paper provides a statistical test for DDMs with general, nonconstant boundaries. As a byproduct, we show that the drift and the boundary are uniquely identified. We use our condition to nonparametrically estimate the drift and the boundary and construct a test statistic based on finite samples.

The drift diffusion model (DDM) is a model of sequential sampling with diffusion (Brownian) signals, where the decision maker accumulates evidence until the process hits a stopping boundary, and then stops and chooses the alternative that corresponds to that boundary. This model has been widely used in psychology, neuroeconomics, and neuroscience to explain the observed patterns of choice and response times in a range of binary choice decision problems. One class of papers study “perception tasks” with an objectively correct answer e.g. “are more of the dots on the screen moving left or moving right?”; here the drift of the process is related to which choice is objectively correct (1, 2). The other class of papers study “consumption tasks” (otherwise known as value-based tasks, or preferential tasks) such as “which of these snacks would you rather eat?”; here the drift is related to the relative appeal of the alternatives (3–11).

The simplest version of the DDM assumes that the stopping boundaries are constant over time (12–15). More recently a number of papers use non-constant boundaries to better fit the data, and in particular the observed correlation between response times and choice accuracy, i.e., that correct responses are faster than incorrect responses (16–19).

Constant stopping boundaries are optimal for perception tasks where the volatility of the signals and the flow cost of sampling are both constant, and the prior belief is that the drift of the diffusion has only two possible values, depending on which decision is correct. Even with constant volatility and costs, non-constant boundaries are optimal for other priors, for example when the difficulty of the task varies from trial to trial and some decision problems are harder than others. (17) show how to computationally derive the optimal boundaries in this case. (18) characterize the optimal boundaries for the consumption task: the decision maker is uncertain about the utility of each choice, with independent normal priors on the value of each option.

This paper provides a statistical test for DDMs with general boundaries, without regard to their optimality. We first prove a characterization theorem: we find a condition on choice probabilities that is satisfied if and only if the choice probabilities are generated by some DDM. Moreover, we show that the drift and the boundary are uniquely identified. We then use our condition to nonparametrically estimate the drift and the boundary and construct a test statistic based on finite samples.

Recent related work on DDM includes (17) who conducted a Bayesian estimation of a collapsing boundary model and (18) who conducted a maximum likelihood estimation. (20) estimate collapsing boundaries in a parametric class, allowing for a random nondecision time at the start. (21) estimate a version of DDM with constant boundaries but random starting point of the signal accumulation process; (22) estimates a similar model where other parameters are made random. (23) partially characterize DDM with constant boundary.

Other work on DDM-like models includes the decision field theory of (24–26), which allows the signal process to be mean-reverting. (27) and (28) study models where response time is a deterministic function of the utility difference. (29–34) study dynamic costly optimal information acquisition.

1. Choice Problems and Choice Processes

The agent is facing a binary choice problem $c$ between action $x$ and action $y$. In consumption tasks $x$ and $y$ are items the agent is choosing between. To allow for presentation effects, we view $c := (x, y)$ as an ordered pair, so $(x, y) \neq (y, x)$; in applications to laboratory data we let $x$ denote the left-hand or top-most action. In perception tasks $x$ and $y$ are the two

*They ignore the issue of correlation between response times and choices by looking only at marginal distributions, which makes their conditions necessary but not sufficient.

Significance Statement

The drift diffusion model (DDM) has been widely used in psychology and neuroeconomics to explain observed patterns of choices and response times. This paper provides the first identification and characterization theorems for this model: we show that the parameters are uniquely pinned down and determine which data sets are consistent with some form of DDM. We then develop a statistical test of the model based on finite data sets using spline estimation. These results establish the empirical content of the model and provide a way for researchers to see when it is applicable.

All authors designed research, performed research, contributed new analytic tools, and wrote the paper. DF, PS, and TS contributed Theorems 1 and 2; WN contributed Theorem 3.

The authors declare no conflict of interest.

1DF, WN, PS, and TS contributed equally to this work.

The drift diffusion model (DDM) is commonly used to explain
we assume that each option is chosen with positive conditional
we define the choice imbalance, 
we assume that both choices are equally likely, 
we assume that each option is chosen with positive conditional
we define the average choice imbalance, 

\[
\overline{I}^c := \frac{1}{\bar{p}^c} \int_0^\infty \bar{I}^c(t) \, dF^c(t),
\]
and \( \bar{p}^c \) to be the average choice probability,
and assume that all of these integrals exist. Finally, we relabel 
\( x \) and \( y \) as needed so that \( x \) is chosen weakly more often, i.e.

\[
\overline{I}^c \geq 0.5 \text{ for all } x, y.
\]

2. DDM representation

The drift diffusion model (DDM) is commonly used to explain

\[
Z_t = \delta t + \alpha B_t, \quad [1]
\]

where \( B_t \) is a standard Brownian motion, so in particular

\[
\tau = \inf\{t \geq 0 : |Z_t| \geq b(t)\}, \quad [2]
\]

i.e., the first time the absolute value of the process \( Z_t \) hits the boundary \( b \). Let \( F^*(t, \delta, b, \alpha) := \mathbb{P}[\tau \leq t] \) be the distribution of the stopping time \( \tau \). Likewise, let \( p^*(t; \delta, b, \alpha) \) be the conditional choice probability induced by Eq. (1) and Eq. (2) and a decision rule that chooses \( x \) if \( Z_t = b(\tau) \) and \( y \) if \( Z_t = -b(\tau) \).

Our goal in this paper is to determine which data is consistent with a DDM representation, and when it is, when the representation can be uniquely recovered from the data.

Definition 1 (DDM Representation). Choice process \((p^c, F^c)\) has a DDM representation if there exists a drift \( \delta^c \), a volatility parameter \( \alpha^c > 0 \) as well as a boundary \( b^c : \mathbb{R} \to \mathbb{R} \) such that for all \( x, y \in X \) and \( t \in \mathbb{R} \)

\[
p^c(t) = p^c(t; \delta^c, b^c, \alpha^c)
\]

and

\[
F^c(t) = F^c(t; \delta^c, b^c, \alpha^c).
\]

The original formulation of the DDM was for perception tasks where the drift \( \delta \) is a function of the strength of the stimulus process in choice problem \( c \). In consumption tasks researchers typically assume that the drift \( \delta \) equals the difference between the utility of the two items, i.e.,

\[
\delta = u(x) - u(y)
\]

for all \( c \equiv (x, y) \), see, e.g., (16). Both formulations require that the boundary is the same for all decision problems. This corresponds to cases where the agent treats each decision problem as a random draw from a fixed environment.†

Many empirical applications of the DDM include an initial deterministic or stochastic “non-decision time” where no decision can be made. Allowing for this initial lag can improve the fit of specific functional forms for the boundary. We do not include it here, because the general boundary we consider here can fit an arbitrarily low probability of a very quick decision, and so is indistinguishable from a model with an initial lag on any finite data set.

We are interested in characterizing which choice processes admit a DDM representation. The following result follows immediately from rescaling \( \delta \) and \( b \).

Lemma 1. If a choice process exhibits a DDM representation for some \( \alpha \), then it also exhibits a DDM representation for \( \alpha = 1 \).

We will thus without loss of generality normalize \( \alpha = 1 \). We write \( p^c(t; \delta, b) \) and \( F^c(t; \delta, b) \) as short-hands for \( p^c(t; \delta, b, 1) \) and \( F^c(t; \delta, b, 1) \).

3. Characterization

Given a choice process \((p^c, F^c)\), define the revealed drift

\[
\delta^c := \sqrt{\frac{I^c}{2T^c}}. \quad [3]
\]

The revealed drift is high when the agent makes very imbalanced choices or tends to decide quickly, and is low for choices that are closer to 50-50 or made more slowly.

†In an optimal stopping model, the shape of the boundary is determined by the agent’s prior over these draws.
When $\delta^c$ is non zero and $(p^c(t) - 1/2)\delta^c > 0$ for all $t$, we define the revealed boundary as

$$\hat{b}^c(t) := \frac{\ln p^c(t) - \ln(1 - p^c(t))}{2\delta^c}.$$  [4]

The revealed boundary follows the log-odds ratio of the agent’s choice at time $t$, which is zero whenever the agent’s choice is balanced and increases in the imbalance of the agent’s choice. The revealed boundary is smaller for pairs with a larger revealed drift. In the knife-edge case where the revealed drift is 0, the revealed boundary is not defined, and our results do not apply. Similarly, for $t$ such that $(p^c(t) - 1/2)\delta^c < 0$, $\hat{b}^c(t) < 0$, and $\delta^c$ is not a well defined boundary.

A. Characterization for a fixed decision problem. Our first result characterizes the DDM for a fixed decision problem $c \in C$ and the revealed drift and boundary will exactly match the true parameters. We rule out the knife edge case where the revealed drift equals zero to ensure that the revealed boundary is well defined.\textsuperscript{1}

**Theorem 1.** For $c$ with $\delta^c \neq 0$ the choice process $(p^c, F^c)$ admits a DDM representation if and only if $\hat{b}^c(t) \geq 0$ for all $t \geq 0$ and

$$F^c(t) = F^c(t, \delta^c, \hat{b}^c).$$

Moreover, if such a representation exists, it is unique (up to the choice of $\alpha$) and given by $\delta^c, \hat{b}^c$.

Thus, the choice process $(p^c, F^c)$ is consistent with DDM whenever the observed distribution of stopping times $F^c$ equals the distribution of hitting times generated by the revealed drift $\delta^c$ and revealed boundary $\hat{b}^c$. Theorem 1 shows that for $\delta^c \neq 0$ the revealed drift and boundary are the unique candidate for a DDM representation. It thus allows us to identify the parameters of the DDM model directly from choice data. This permits the model to be calibrated to the data without computing the likelihood function, which requires computationally costly Monte-Carlo simulations. More substantially, as Theorem 1 connects the primitives of the model directly to data it allows us to better understand both the model and the estimated parameters. The estimated drift in the DDM model is a measure of how imbalanced and quick the agent’s choices are, and the shape of the estimated boundary follows the imbalance of the agent’s choices over time. This interpretation makes the empirical content of the parameters of DDM model more transparent and the model thus more useful. Moreover, as we show in Section 4, Theorem 1 allows us to test whether the true data generating process is indeed a DDM.

Note that this theorem shows that the distribution of stopping times contains additional information that is not captured by the mean. For example, a choice process where $p^c(t)$ and $T^c$ are any two given constants is only consistent with one possible distribution of stopping times $F^c$. A test based only on the mean choice probability and mean stopping time will accept any model that matches those two numbers, and in particular will accept a constant boundary regardless of how the choice probability varies over time, thus leading to false positives.

\textsuperscript{1}If the revealed drift equals zero, one needs to recover the boundary from the distribution of decision times $F^c$. This is an open problem in the mathematical literature. See Appendix A for further discussion.

B. Characterization for consumption tasks. Here $X$ is the set of consumption alternatives, and each choice problem $c$ consists of a pair of alternatives, so, in this section we index choice problems by superscript $xy$. For consumption tasks we assume that the order of the items does not matter. This is formally equivalent to a condition that we call symmetry:

$$p^{xy}(t) = 1 - p^{yx}(t)$$

and $F^{xy}(t) = F^{yx}(t)$ for all $t \in \mathbb{R}, x, y \in X$.

**Definition 2 (DDM Representation).** A choice process $(p^{xy}, F^{xy})_{x,y \in X}$ has a choice-DDM representation if there exists a utility function $u : X \to \mathbb{R}$, and a boundary $b : \mathbb{R} \to \mathbb{R}$, such that for all $x, y \in X$ and $t \in \mathbb{R}$

$$p^{xy}(t) = p^x(t, u(x) - u(y), b)$$

and $F^{xy}(t) = F^x(t, u(x) - u(y), b)$.

**Theorem 2.** Suppose that the choice process $(p^{xy}, F^{xy})_{x,y \in X}$ has $\delta^{xy} \neq 0$ for all $x, y \in X$. It has a choice DDM representation if

(i) it is symmetric,

(ii) $F^{xy}(t) = F^x(t, \delta^{xy}, \hat{b}^{xy})$ for all $t \geq 0$,

(iii) $\hat{b}^{(x,y)}(t) = \hat{b}^{(z)}(t)$ for all $x, y, z \in X$ and all $t \geq 0$,

(iv) $\delta^{(x,y)} + \delta^{(y,z)} = \delta^{(x,z)}$ for all $x, y, z \in X$.

Thus, in addition to satisfying the condition from Theorem 1 pairwise, we have two additional consistency conditions imposed across pairs. Condition (iii) follows from our assumption that the agent uses the same stopping boundary in every menu. Condition (iv) comes from the assumption that the drift in a given menu depends on the difference of utilities, that is $\delta^{xy} = u(x) - u(y)$.\textsuperscript{2}

An analogous exercise could be done for perception tasks. Here condition (i) would be dropped and (iv) would be replaced with a condition that specifies the drift as a (potentially parametric) function of the stimulus in choice problem $c$.\textsuperscript{3}

4. A Statistical Test for a Fixed Pair of Alternatives

The test we give is based on comparing model predictions with data estimates. We construct estimators of the drift and boundary for this test, that are of interest in their own right. Constructing these estimators is greatly aided by the explicit formulas for the drift and boundary given in Eq. (3) and Eq. (4). We estimate choice probabilities nonparametrically and plug them in the formulas, replacing expectations with sample averages, to estimate the revealed drift and boundary. We then simulate many stopping times using the drift and boundary estimates. Simulation consistently estimates averages implied by the model, as in (37) and (38). We form a chi-squared test based on differences of the average over the simulations and over the sample of functions of the stopping time.

\textsuperscript{2}The proof of Theorem 2 follows from Theorem 1 and the Sincov functional equation, see, e.g., (35).

\textsuperscript{3}Other exercises along these lines are possible. For instance, (36) models consumption-tasks by an accumulator model where the item-specific signals are correlated. This amounts to dropping conditions (ii) and (iv) since it is equivalent to DDM where both the drift and the boundary depend on $x$ and $y$. 

A. Estimation of drift and boundary. An essential ingredient for the drift and boundary estimators and for the test of the model is an estimator of the choice probability $p^*(t)$ conditional on decision occurring at time $t$. We focus on a linear probability estimator $\hat{p}(t)$ obtained as the predicted value from a linear regression of observations of the choice indicator data (a vector of zeros and ones) on functions of $t$. This estimator will be nonparametric by virtue of using flexible regressors that are designed to approximate any function. We consider both power series and piecewise linear functions for the regressors. To describe the estimators and the test, let the data consist of $n$ observations $(\tau_1, \gamma_1), \ldots, (\tau_n, \gamma_n)$ of the decision time $\tau$ and an indicator variable $\gamma_i \in \{0, 1\}$ that is equal to 1 if choice $d$ is made and 0 otherwise, for $i = 1, \ldots, n$. We construct $\hat{p}(t)$ from a linear regression of $\gamma_i$ on functions of $G(\tau)$, where $G(\tau)$ is a strictly increasing cumulative distribution function (CDF) that lies in the unit interval $[0, 1]$. Use of $G(\tau)$ allows for unbounded $\tau_i$. The resulting choice probability estimator $\hat{p}(t)$ is described in detail in an Appendix. Conditions for $\hat{p}(t)$ to be consistent and have other important large sample properties are given in Assumptions 2 and 3 to follow.

We estimate the revealed drift $\delta$ by plugging in $\hat{p}(t)$ for $p^*(t)$ in formula Eq. (3) and replacing expectations with sample averages. Let

$$\hat{I}(t) := \hat{p}(t) \ln \left[ \frac{\hat{p}(t)}{1 - \hat{p}(t)} \right] + [1 - \hat{p}(t)] \ln \left[ \frac{1 - \hat{p}(t)}{\hat{p}(t)} \right],$$

$$\hat{\tau} := \frac{1}{n} \sum_{i=1}^{n} \hat{\tau}_i.$$

The estimator of $\delta$ is then

$$\hat{\delta} := \sqrt{\hat{I}/2\hat{\tau}}.$$

The estimator of the boundary $b(t)$ is obtained by plugging in $\hat{\delta}$ and $\hat{p}(t)$ in the expression of equation Eq. (4), giving

$$\hat{b}(t) := \frac{1}{2\hat{\delta}} \ln \left[ \frac{\hat{p}(t)}{1 - \hat{p}(t)} \right].$$

B. Testing. The test is based on comparing sample averages of functions of stopping times from the data with simulated averages implied by the estimators of the revealed drift and boundary. To describe the test let $m_j(\tau) = (m_{1j}(\tau), \ldots, m_{Sj}(\tau))'$ be a $J \times 1$ vector of functions of $\tau$. Examples of $m_j(\tau)$ include indicator functions for intervals and low order powers of $G(\tau)$. A sample moment vector is $\hat{m} = \sum_{i=1}^{n} m_j(\tau_i)/n$. To describe the simulations let $B_1^S, \ldots, B_B^S$ be $S$ independent copies of Brownian motion and

$$\hat{\tau}_S := \inf\{t \geq 0 : |\delta \hat{b} + \hat{b}(t)| \geq \hat{b}(t)\}.$$

A moment vector predicted by the model is $\hat{m}_S := \sum_{i=1}^{n} m_j(\hat{\tau}_S)/S$. Let $\hat{V}$ be a consistent estimator of the asymptotic variance of $\sqrt{n}(\hat{m} - \hat{m}_S)$ when the model is correctly specified, as we will describe below. The test statistic is

$$A := n(\hat{m} - \hat{m}_S)\hat{V}^{-1}(\hat{m} - \hat{m}_S).$$

The model would be rejected if $A$ exceeds the critical value of a $\chi^2(J)$ distribution.

If $J$ is allowed to grow slowly with $n$ and $m_j(\tau)$ is allowed to grow in dimension and richness as $n$ grows then this approach will test all the restrictions implied by DDM as $n$ grows. If $m_j(\tau)$ is chosen so that any function of $\tau$ can be approximated by a linear combination $c_j m_j(\tau)$ as $J$ grows then the test must reject as $J$ grows when the DDM model is incorrect. An incorrect DDM model will imply $c_j \hat{m}$ and $c_j \hat{m}_S$ have different probability limits for some $c$ and $J$ large enough. Also, $A \geq n(c^2(\hat{m} - \hat{m}_S)/\hat{V} + c^2 \hat{V} c^2)$, so $A$ grows as fast as $n$. Restricting $J$ to grow slowly with $n$ makes the test reject for large enough $n$.

It is straightforward to construct $\hat{V}$ using the bootstrap. Each bootstrap replication starts with a random sample $Z_{n,i}^B = (\tau_{1i}^B, y_{1i}^B), \ldots, (\tau_{ni}^B, y_{ni}^B)$ consisting of i.i.d. observations $(\tau_i^B, y_i)$, $(i = 1, \ldots, n)$, drawn at random with replacement from the data observations. Here $j$ is a positive integer that denotes the bootstrap replication with $j = 1, \ldots, B$, so there are $B$ replications. For the $j^*$th replication $G_j^B, \hat{p}(t), \hat{b}(t), \hat{b}(t)$, and $\hat{m}$ are computed exactly as above except with $Z_{n,i}^B$ replacing the actual data. Using drift coefficient $\hat{\delta}^*$ and the estimated boundary $\hat{b}(t)$ from the $J^*$th bootstrap replication, $S$ simulations $\hat{m}_j^B, (s = 1, \ldots, S)$, are constructed as described above, resimulating for each bootstrap replication, and $\hat{m}_j^S := \sum_{s=1}^{S} m_j(\hat{\tau}_S^s)/S$ calculated. For $\Delta := \hat{m}_j - \hat{m}_j^S$ and $\Delta^* := \sum_{j=1}^{J} \hat{b}_j^B$ a bootstrap variance estimator $\hat{V}_B$ is

$$\hat{V}_B = \frac{n}{B} \sum_{j=1}^{J} (\Delta_j - \Delta_j^*) (\Delta_j - \Delta_j^*)'.$$

In Section 3 of SI we give another estimator $\hat{V}_n$ based on asymptotic theory. In simulations of synthetic data to follow we find that the bootstrap estimator $\hat{V}_B$ leads to rejection frequencies that are closer to their nominal values, so we recommend the bootstrap estimator variance estimator $\hat{V} = \hat{V}_B$ for constructing $A$ in practice.

The test statistic is based only on the distribution of decision times, and does not involve model choice probabilities and alternatives chosen in the data. This feature of the test does not affect its power to detect failures of the DDM model, because the choice probabilities for the estimated DDM model are equal to the nonparametric estimates $\hat{p}(t)$. To see this result note that there is a one-to-one relationship between the revealed boundary and the choice probabilities (given the revealed drift), with revealed choice probabilities given by

$$\hat{p}(t) = \frac{\exp(2\hat{\delta}^* \hat{b}(t))}{\exp(2\hat{\delta}^* \hat{b}(t)) + 1}.$$
functions for disjoint intervals. Let \( \tau_{j,J} = G^{-1}(j/(J+1)) \) \((j = 0, \ldots, J)\), \( \tau_{J+1,J} = \infty \). Consider
\[
m_{j,J}(t) = \sqrt{J+1} - \chi(\tau_{j,J} \leq t < \tau_{j+1,J}), \quad (j = 1, \ldots, J).
\]
The test based on these functions is based on comparing the empirical probabilities of intervals with those predicted by the model. The normalization of multiplying by \( \sqrt{J+1} \) is convenient in making the second moment of these functions of the same magnitude for different values of \( J \). Note that we have left out the indicator for the interval \((0, 1/(J+1))\). We have done this to account for the fact that the estimator of the drift parameter uses some information about \( \tau_i \), so that we are not able to test all of the implications of the DDM for the distribution of \( \tau_i \); we can only test overidentifying restrictions. Also in the Monte Carlo results we left out the indicator for the interval \((J/(J+1), 1)\). Leaving out this other endpoint makes actual rejection rates closer to the nominal ones in our Monte Carlo study.

We derive results under the following conditions:

**Assumption 1.** The data \((\tau_1, \tau_2, \ldots, \tau_n)\) are i.i.d.

This is the basic statistical condition that leads to the data being more informative as the sample size \( n \) grows.

**Assumption 2.** The pdf of \( G(\tau_i) \) is bounded and bounded away from zero.

This assumption is equivalent to the ratio of the pdf of \( \tau_i \) to \( dG(t)/dt \) being bounded and bounded away from zero. It is straightforward to weaken this condition to allow it to only requiring it on a compact, connected interval that is a subset of \((0, 1)\), if we assume the \( b(t) \) is constant on known intervals near 0 and where \( \tau \) is large.

We also make a smoothness assumption on the boundary function.

**Assumption 3.** \( b(G^{-1}(g)) \) is bounded and \( s \geq 1 \) times differentiable with bounded derivatives on \( g \in [0, 1] \) and the \( q_{k,k}(G) \), \( k = 1, \ldots, K \) are b-splines of order \( s-1 \).

This condition requires that the derivatives of \( b(t) \) go to zero in the tails of the distribution of \( \tau_i \) as fast as the pdf of \( G(t) \) does. We also require that the drift parameter be nonzero.

**Assumption 4.** \( \delta \neq 0 \).

This assumption is clearly important for the revealed boundary formula in equation (revealed boundary formula). When \( \delta = 0 \) this formula does not hold, \( p^d(t) = 1/2 \) for all \( t \), and the boundary need not be constant. Consequently the test given here would not be correct. Given this sensitivity of model characteristics to \( \delta \neq 0 \) it may make sense to test the null hypothesis that \( \delta = 0 \). This null hypothesis can be tested using the estimator \( \hat{\delta} \) and the bootstrap standard error \( SE_B(\hat{\delta}) = \{\sum_{j=1}^{B} (\hat{\delta}_j - \hat{\delta})^2 / B\}^{1/2} \). A t-statistic \( \hat{\delta} / SE_B(\hat{\delta}) \)
that is substantially greater than the standard Gaussian critical value of 1.96 would provide evidence that \( \delta \neq 0 \).

We need to add other conditions about the smoothness of CDF of \( \tau_i \) as a function of the drift \( \delta \) and the boundary and about rates of growth of \( J \) and \( K \). They involve much notation, so we state them in Assumption 5 in Appendix C.

We can now state the following result on the limiting distribution of \( \hat{\delta} \) for the asymptotic variance estimator \( \hat{V} = \hat{V}_n \) described in SI, Section 3.

**Theorem 3.** Suppose that Assumptions 1, 2, 3, 4 and Assumption 5 in Appendix C are satisfied. Then for the \( 1 - \alpha \) quantile \( c(\alpha, J) \) of a chi-square distribution with \( J \) degrees of freedom
\[
\mathbb{P} [ \hat{\delta} \geq c(\alpha, J) ] \rightarrow \alpha.
\]

This test could be extended to multiple-alternatives settings along the lines of Theorem 2, but we do not do so here.†

### 5. Examples for Synthetic Data

To consider how the estimators and test might work in practice we carry out some simulations where synthetic data was repeatedly generated from a DDM model. In the DDM model we set \( \delta_0 = .5 \) throughout and set the boundary to be constant at \(-1 \) and 1. We set the sample size to be \( n = 1000 \) in each case. We consider three different boundary estimators: a constant boundary estimator where \( \hat{\delta}(t) \) is the sample proportion that alternative 1 is chosen, a \( \hat{\delta}(t) \) depending on cubic functions \((1, G, G^2, G^3)^t\), and a continuous, piecewise linear function of \( G \) where the slope can change when \( G \) equals either .33 and .66. We repeat the generation of the simulated data and calculation of the estimators and test 500 times for each case.

![Figure 2: Boundary function estimation](image-url)
and piecewise linear boundaries seem large but are consistent with large sample approximations, as discussed in the Supplemental Information. In the Supplemental Information we find that \( \hat{\delta} \) is a precise estimator of the drift parameter for sample size \( n = 1000 \).

Table 1 reports Monte Carlo rejection frequencies for the test statistic with bootstrap variance estimator. The \( \hat{p}(t) \) is either does not depend on \( t \) or depends on piecewise linear functions of \( G(t) \) with either no slope change, one slope change at \( G = .5 \), or two slope changes at \( G = .33 \) and .66. We consider the test statistic with bootstrap variance estimator \( \hat{V}_p \) obtained from \( B = 250 \) bootstrap replications. We set \( J = 5 \) with only the middle three intervals included in the test statistic and \( J = 8 \) where only the middle six intervals are included. Rejection frequencies are given when critical values are chosen using the asymptotic chi-squared approximation with nominal rejection frequencies of 1, 5, 10, and 20 percent.

The acceptance regions for a test of level .01 that the rejection frequencies are equal their asymptotic values are .010 ± .006, .050 ± .016, .100 ± .022, .200 ± .030 for asymptotic levels .01, .05, .10, and .20 respectively. We find some tendency of the test statistic to reject too often when the number of intervals \( J \) is larger and the number of slope changes is larger. We found in additional simulations not reported here that for \( \hat{p}(t) \) cubic in \( G \) or the analytic \( \tilde{V} \) the test statistic tended to overreject even more, especially for the analytic variance estimator. In the Appendix we discuss additional simulation results for \( J = 5 \) for a DDM model with an exponential boundary and for a Poisson model. There we find that the test has good power against the Poisson model, but shows little tendency to reject the DDM model with exponential boundary for \( \hat{p}(t) \) piecewise linear in \( G \) with two slope changes. We also give rejection frequencies for the test for smaller sample sizes \( n = 250 \) and \( n = 500 \). There we find that the large sample approximation remains quite accurate for the smaller sample sizes for a constant and linear boundary specification, but the approximation is considerably worse than for \( n = 1000 \) when slope changes are included.

The tendency Table 2 to overreject for larger \( J \) and/or more flexible boundary specifications indicates some difficulty in reliably testing the many implications of the DDM model from 1000 observations. This difficulty is not surprising given the high variance of the boundary estimator, which could lead to the local approximation used in the asymptotic theory not working well. Imposing restrictions on the boundary could help with this problem as it does in Table 2, where more parsimonious specifications have less tendency to overreject. One potentially useful nonparametric restriction is monotonicity of the boundary. One could impose such a restriction and carry out inference using the approach of (42). This avenue seems potentially fruitful but is beyond the scope of this paper.

### Appendix

#### A. Choice Problems with Zero Drift

We next provide a partial extension of Theorem 1 to the knifedge case where the revealed drift equals zero along with some further discussion. When the drift in the DDM model is 0, \( p(t) = 1/2 \) for all \( t \geq 0 \), due to the symmetry of the problem. This implies the following extension of Theorem 1:

**Theorem 4.** For \( c \) with \( \delta^c = 0 \) the choice process \( (p^c, F^c) \) admits a DDM representation if and only if \( p^c \equiv 1/2 \) and there exists \( \tilde{b}^c \) such that for all \( t \geq 0 \)

\[
F^c(t) = F^c(t, \delta^c, \tilde{b}^c).
\]

In this case the boundary is not revealed by the choice probability. The question of how to recover the boundary from the distribution of stopping times is known as the “inverse first-passage time problem”. The, existence and uniqueness of the boundary remains an open problem even in the simplest case of a one-sided boundary and a Brownian motion with drift (see the introduction in (43)). Most closely related to our work is (44) whose Theorem 3.1 (under some regularity conditions) connects the boundary and the distribution over choice times in our model through a non-linear volterra integral equation.

#### B. The Choice Probability Estimator

The choice probability estimator \( \hat{p}(t) \) considered here is the predicted value from from a linear regression of \( \gamma_i \) on functions of \( G(\tau_i) \). To describe \( \hat{p}(t) \) let a \( K \times 1 \) vector of functions with domain \([0, 1]\) be

\[
q^K(G) = (q_{1K}(G), \ldots, q_{KK}(G))'.
\]

For example, \( q^K(G) \) could consist of powers of \( G \) or be piecewise linear functions of the form \( 1, G, \) and \( G(G - \ell_{k-2})(G - \ell_{k-2}) \), \( (k = 3, \ldots, K) \). The \( \hat{p}(t) \) we consider is

\[
\hat{p}(t) := q^K(G(t))' \hat{\beta}, \quad q^K = q^K(G(\tau_i)),
\]

\[
\hat{\beta} := \left( \sum_{i=1}^n q_i^K q_i K' \right)^{-1} \sum_{i=1}^n q_i^K \gamma_i.
\]

The transformation \( G(\tau) \) to the unit interval helps \( \hat{p}(t) \) be a good estimator with unbounded \( \tau \). It is helpful for this purpose to have \( G(\tau_i) \) be quite evenly distributed over the unit interval, as near to uniform as possible. One possible choice of \( G(\tau) \) is the cumulative distribution function of the first passage time of a Brownian motion with drift crossing a single boundary, with mean and variance matched to that of the \( \tau_i \) distribution. Figure 1 gives a histogram for \( G(\tau_i) \) from 100,000 simulations of \( \gamma_i \) for drift \( \delta_0 = .5 \) and a constant boundary of \( -1 \) and 1.

The histogram is bounded well away from zero and infinity over most of its range so that we expect the linear probability estimator based on this \( G(\tau) \) should work well. The histogram does suggest that the density may grow as \( G(\tau) \) approaches zero and shrink and \( G(\tau) \) approaches 1. We expect this tail behavior to have little effect on finite sample performance of the estimator. It could also be controlled for if the boundary is constant as \( \tau \) approaches zero and infinity and that restriction is imposed on the boundary estimator.
C. Smoothness Conditions for the CDF of $\tau_i$

To obtain the limiting distribution of the test statistic we make use of smoothness conditions for the CDF of $\tau_i$ as $F^*(t, \delta, b; t)$ as a function of the drift $\delta$ and boundary $b(t)$. The three key primitive regularity conditions that will be useful involve a Frechet derivative $D(\delta - \delta, \tilde{b} - b; \delta, b, t)$ of $F^*(t, \delta, b)$ with respect to $\delta$ and $b$. We collect these conditions in the following assumption. Let $\varepsilon_n = \sqrt{n^{-1}K \ln(K)} + K^{-n}$.

Assumption 5. For $|\tilde{b}| = \sup_t |\tilde{b}(t)|$ there is $C > 0$ not depending on $\delta, b, t$ such that

a) $|F^*(t, \delta, \tilde{b}) - F^*(t, \delta, b) + D(\delta - \delta, \tilde{b} - b; \delta, b, t)| \leq C(|\delta - \delta|^2 + |\tilde{b} - b|^2)$;

b) for each $t$ there is a constant $D^0_{\alpha,t}$ and function $a_0(t)$ such that $|a_0(\tau)| < C, |D^0_{\alpha,t}| \leq C, |d^s a_0(t) / dt^s| \leq C$ for $s$ equal to the order of the spline plus 1, and

$$D(\delta - \delta, \tilde{b} - b; \delta, b, t) = D^0_{\alpha,t}(\delta - \delta) + E|a_0(\tau)| \{b(\tau) - b(\tau)\};$$

c) $|D(\delta, b, \tilde{b}, \tilde{b}, b) - D(\delta, b, \delta_0, \tilde{b}, b_0)| \leq C(|\delta - \delta_0| + |b - b_0|)$;

d) There is $C > 0$ such that for $\psi_{1,\delta} = I(\tau) = E[I(\tau)] - \delta^2 (\tau_i - E[\tau_i])$ and all $J$,

$$(J + 1)E[\psi_{1,\delta}^2 < 1/(J + 1)] \psi_{1,\delta}^2 \geq C.$$

e) Each of the following converge to zero: $\sqrt{\pi} J^1 \psi_{\alpha,\tilde{b}}, n J^3 / S$, $J^7 / K^2 (\sqrt{\pi} \Delta), J^7 / K \Delta, J^7 / K^3 \psi_{\alpha,\tilde{b}}, J^5 / K^\infty$.

Part a) is Frechet differentiability of the CDF of $\tau_i$ in the drift and boundary, b) is implied by mean square continuity of the derivative and the Riesz representation Theorem, and c) is continuity of the functional derivative $D$ in $\delta$ and $b$. The test statistic will continue to be asymptotically chi-squared for a stronger norm for $b$ under corresponding stronger rate conditions for $J, K, \Delta$.

D. Additional Tests on Synthetic Data:

Table 2 gives rejection frequencies for the test on synthetic data from a DDM model with constant boundary, an exponential boundary $b(t) = 1 / 2 + 2 \exp(-3t/2)$, and a Poisson process. The Poisson process has $p(t) = e^{-\lambda} / (e^{-\lambda} + e^{-X})$ and $F^*(t) = 1 - e^{-\lambda t}$ for $\lambda = e^{-\lambda} + e^{-X}$, with $a$ and $b$ chosen to that $p(t)$ and $E[\tau]$ match those of DDM model with drift $1/2$ and $b(t) = 1$.

Table 2 differs from Table 1 in one boundary slope changing at the sample median of $G(\tau_1), \ldots, G(\tau_n)$ rather than at .5 and two slopes changing at the .33 and .66 quantiles rather than at the values .33 and .66. Results in Table 2 are for $J = 5$ only. We continue to use $B = 250$ bootstrap replications and report results for 500 synthetic data set replications.

We find that for the DDM model with a constant boundary the test rejection frequencies increase as the specification of the boundary becomes richer, as in Table 1. Remarkably, for a DDM model with exponential boundary and a piecewise linear estimator with two slope changes, the rejection frequencies are similar to those where the boundary was constant. Thus, in this example specifying an incorrect piecewise linear boundary does not make the asymptotic approximation worse. We also find that the test has good power against a Poisson model, with the rejection frequencies being much larger when the data is generated by a Poisson model than when the data is generated by a DDM model.

To see the effect of smaller samples on the large sample approximation we also carried out simulations for $n = 250$ and $n = 500$ for the DDM model with constant boundary and $J = 5$. These results are reported in Table 3.

We find that the large sample approximation remains quite accurate for the smaller sample sizes for a constant and linear boundary specification but the approximation is considerably worse than for $n = 1000$ when slope changes are included.
