Abstract

This paper studies the distribution of firm productivity and production in a network of geographic locations. Using firm-level data from China’s manufacturing sector from 1998 to 2007, we document that, on average, firms’ geographic locations explain approximately 14% of the productivity dispersion, yet the explanatory power of locations varies significantly across industries. These empirical patterns motivate us to develop two “market access” measures in a firm heterogeneity and trade framework to illustrate how changes in inter-location trade costs affect the selection of firms in each location and shape the distribution of firm productivity and production across locations. A decrease in a location’s trade cost with other locations improves its (1) consumer market access (CMA), a measure of import competition that local firms face from rival firms elsewhere; and (2) firm market access (FMA), a measure of the size of the export market for local firms. To distinguish between these two competing effects empirically, we use reduction in road travel time due to massive nationwide highway construction as a source of variation in trade costs between Chinese prefectures. Reduced-form evidence supports theoretical predictions that better CMA is associated with higher local average productivity and smaller output of local individual firms, while better FMA with lower average productivity and larger firm output. Counterfactual analysis suggests that, for the manufacturing sector on aggregate, the expansion of highway networks accounted for 24% of the observed rise in productivity level, 40% of the decline in productivity dispersion, and 16% of the increase in output, but these effects differ substantially across industries and locations.

*Wentao Xiong is deeply indebted to his advisers Shawn Cole, Edward Glaeser, and Elhanan Helpman for their invaluable advice and continued support. We would like to thank Pol Antras, Jie Bai, Marco Pagano, Kirill Borusyak, Raj Chetty, Alonso De Gortari, Xiang Ding, Richard Hornbeck, Andrew Garin, William Kerr, Michael Kremer, Marc Melitz, Nathan Nunn, Martin Rotemberg, and participants at Harvard economics department’s international, public, development, and informal practice seminars for many helpful suggestions. Errors are solely our own.
1 Introduction

This paper studies the distribution of firm productivity and production in the network of geographic locations in an economy. It is well documented that there exists substantial dispersion of firm productivity within narrowly defined industries (see Bernard et al. (2007, 2012) for reviews). While there have been attempts to investigate the causes underlying such dispersion, research work to date is far from exhaustive. Meanwhile, a vast literature in economic geography explores the spatial distribution of production activities, and frequently links firms’ location choices to their productivity (see Rosenthal & Strange (2004) and Puga (2010) for reviews).

This paper highlights the under-studied role of geography from an inter-regional trade perspective: trade costs between locations affect where firms are located, influence the selection of firms that enter and produce in each location, and hence shape the geographic distribution of firm productivity and production in an economy. Formally, we further develop the “market access” approach Donaldson & Hornbeck (2016) in a Melitz (2003) framework to capture the effects of trade cost changes in general equilibrium. We first derive simple expressions of two types of market access: consumer market access (CMA) that measures competition from rival firms, and firm market access (FMA) that measures market size available to local firms. We then use the dramatic expansion of highway networks in China from 1998 to 2007 as a source of variation in Chinese prefectures’ market access, and examine how the geographic distribution of manufacturing firms’ productivity and production evolved accordingly.

We start by establishing two empirical patterns related to how firm productivity and production are distributed across geographic locations. Our empirical setting is the Chinese manufacturing sector from 1998 to 2007, and “geographic locations” refer to prefectures. First, geographic locations explain a significant fraction of between-firm productivity variation. On average across industries, where firms are located accounts for approximately 14% of the variation in firm productivity, yet this fraction ranges from below 2% for some industries to above 20% for some others. Second, while firms tend to be geographically concentrated, the degree of concentration again differs substantially by industry. Some industries have over 50% of total sales from firms in fewer than 5 locations, some have their sales spread out among firms in more than 200 locations, with no location accounting for more than 2% of industry aggregate.

A prefecture usually consists of 2 – 4 core urban districts and 4 – 8 surrounding counties, similar to a commuting zone in the U.S.A.
The stylized facts above provoke inquiry into the underlying mechanisms through which geographic locations matter. This paper tackles this question from an inter-regional trade perspective. Changes in inter-location trade costs induce two counteracting effects on firm productivity distribution and production in each location. As trade costs decline, on the one hand, local consumers will find it less expensive to buy from rival firms in other locations, or equivalently, local firms will face more competition from elsewhere (“import competition”). For each location, stronger import competition only allows the more productive firms to enter and produce, raises local average productivity, and shrinks each surviving firm’s output. On the other hand, local firms can also more easily sell to markets elsewhere (“export access”). For each location, better export access allows less productive firms to survive, lowers local average productivity, and increases each surviving firm’s output. Despite their countervailing effects, import competition and export access are also inter-related via an income-expenditure link: the more productive firms there are in a location, the higher competitive pressure these firms exert on firms in other locations; meanwhile, more productive firms bring in more revenue for local consumers, who can thus spend more on purchases from firms elsewhere.

This paper formalizes the intuition above by extending the “market access” approach per Donaldson & Hornbeck (2016) in the firm heterogeneity and trade framework of Melitz (2003). We derive two distinct market access measures: consumer market access (CMA) to capture import competition, and firm market access (FMA) to capture export access. For a location, both market access measures increase in another location’s economic mass, for example the number of competing firms or the total purchasing power of consumers, and decrease in the trade cost between the two locations. A location’s market access affects its local productivity distribution and production via firm selection: as trade costs decline, better CMA makes it more difficult for less productive firms to survive and compresses the output of surviving firms, while better FMA works in the opposite direction. As local firms respond to trade cost shocks, they generate spillovers on firms elsewhere in the network of locations, even if some other locations do not experience trade cost changes directly. For example, consider 3 locations o, m, and d that trade with one another. If many new firms enter in o after a highway connects o and d, these firms will exert higher competitive pressure on rival firms in m (an increase in m’s CMA), even if m is not connected to the o – d highway. As less productive firms exit from m, m gives less intense competition to d, attracting more entrants in d, which can then feed back to firm selection in o. Such inter-location interaction necessitates our
To calibrate and test the model, this paper exploits a common and important source of variation in trade costs: construction of transportation infrastructure. Specifically, in the decade from 1998 to 2007, along with a 5-fold increase in aggregate manufacturing output, China witnessed dramatic growth in its highway networks, with only sporadic regional highways at the beginning but a well connected nationwide highway system in the end. We treat each prefecture as a local economy, and approximate the trade costs between them using road travel time, which highway networks reduced by over 40% on average across prefecture pairs in this period. Market access measures are then defined at industry-prefecture level. The historic expansion of China’s manufacturing sector and highway networks resulted in substantial changes in both CMA and FMA, with sizable variation in such changes across industry-prefecture’s.

We use firm-level data and inter-prefecture travel time data for model calibration, allowing the empirical relationship between trade cost and travel time to differ across industries. We find that trade cost increases in travel time, with a steeper slope for industries whose products have higher weight-to-value ratios, a proxy for the per-unit-value price of road transport, and industries for which expenses on road transport account for a larger fraction of total input. We then use the resulting parameter estimates to compute market access measures and investigate how they are correlated with firm productivity distribution and production at industry-prefecture level, which yields 3 sets of reduced-form evidence consistent with the theoretical predictions above. First, holding FMA constant, CMA exhibits a strong positive correlation with local average productivity, with an increase of 1 standard deviation (s.d.) in CMA corresponding to about 0.24 s.d increase in local mean productivity. In contrast, holding CMA constant, an increase of 1 s.d. in FMA is associated with 0.18 s.d. decrease in local mean productivity. The correlations between market access and local average productivity are higher for high weight-to-value industries. Second, conditional on an individual firm’s own productivity, FMA exhibits a strong positive correlation with this firm’s output, with 1 s.d. increase in FMA corresponding to 0.32 s.d. increase in firm output, and this effect comes mostly from highly productive firms. Third, an increase in CMA or a decrease in FMA is related to a higher probability of exit among less productive firms and a smaller number of entrants.

A key concern about the causal interpretation of the reduced-form evidence above is that changes in a location’s market access are endogenous to changes in local productivity and produc-
tion outcomes. For instance, the government may choose to build highways to connect prefectures where firms are becoming more productive. To start with, we show that baseline prefecture characteristics, such as per-capita GDP and population density, do not predict when a prefecture receives highway connection. Furthermore, we define two alternative sets of market access measures that are less correlated with local economic prospects. First, when computing market access measures, we exclude prefectures that are geographically close to the prefecture in question. While a prefecture’s market access may comove with economic trends locally and in nearby areas, changes in market access due to “distant neighbors” are less correlated with changes in the local economy. Second, we use contemporary trade cost, but keep economic mass of markets elsewhere at baseline. In this way, changes in market access only come from changes in trade cost, not other locations’ economic conditions. Our reduced-form results are robust to alternative definitions of market access.

To characterize the new equilibrium after a trade cost shock, we rely on our structural model to recover counterfactual scenarios, incorporating interaction among locations in the network. For our main counterfactual, we assume that 2007 highway networks were put in place in 1998, and examine how 1998 geographic distribution of firm productivity and production would have responded. In this scenario, the dispersion of firm productivity across locations is significantly reduced, production is concentrated in slightly fewer locations, and aggregate productivity and output levels are much higher. This overall trend masks considerable heterogeneity across industries and locations. For instance, productivity dispersion decreases more for industries with a higher share of output in (often inefficient) state-owned enterprises, and locations where firms are highly productive tend to see a larger increase in total output. We then compare this counterfactual, where only market access forces have been at work, with the actual 2007 firm-level data. We find that, for the manufacturing sector overall, the highway-induced market access dynamics alone accounts for a significant fraction of the observed changes between 1998 and 2007: around 24% of productivity growth, 40% of the decline in productivity dispersion, and 16% of output growth.

Emphasizing import competition and export access effects, we are missing some potentially important impacts of highway construction that we can’t measure due to data limitations. For example, highway networks can encourage firms to cluster in certain regions and create more benefits of agglomeration, improve access to locations from which firms source intermediate inputs, raise

---

2 In Appendix A.1.2, we supplement our main model by adding an input channel, and derive an expression for input market access (IMA) that captures the effect of input price changes in response to trade cost shocks. We also discuss what data we need to empirically estimate this more comprehensive model.
individual firms’ productivity levels by making it more convenient for experienced technicians to travel between locations and exchange ideas, etc. We focus on import competition and export access to keep our theoretical framework simple, tractable, and easy to estimate given our data. In fact, this seemingly narrow focus can explain a significant fraction of the observed productivity and production evolution, as shown in the counterfactual analysis above.

This paper connects two vast fields of active research: economic geography and firm heterogeneity. The spatial distribution of economic activities, and most relevant to this paper, firms, has long taken center stage in economic geography, and has been frequently linked to firms’ productivity. In firm heterogeneity literature, the sizable dispersion of firm productivity has been repeatedly highlighted, and remains prominent in research on international trade.

A voluminous literature on economic geography has proposed various theories why firms choose to locate where they are, and many theories suggest that firms choose to locate where they can be most productive. Puga (2010) comprehensively reviews studies on the magnitude and causes of the geographic concentration of production activities. This paper stresses that, by determining where to locate, firms choose how close they are to their competitors and product markets, and affect other firms’ location choices. A location where firms can be highly productive may seem less ideal if many competitors are nearby or product markets are distant. In other words, a location attracts firms not only because of its (immobile) endowment, but also because of its connection with other locations, and better connection often means lower trade costs. Redding & Turner (2015) offers a detailed review of transportation costs and the spatial organization of economic activity.

Directly contributing to the extensive research on firm heterogeneity (see Bernard et al. (2012) for an overview), this paper documents the important yet understudied role of geography in shaping firm productivity distribution. Many papers offer explanations of the enormous difference in productivity between firms, such as technology (Eaton & Kortum, 2002), policy distortions (Hsieh & Klenow, 2009), management practice (Bloom et al., 2013), labor mobility (Tombe & Zhu, 2015), etc. This paper focuses on an unexplored factor, namely geography-based market access, distinguishes between CMA and FMA, and discusses the respective implications for productivity distribution.

Using highway connection as an important source of variation in market access, this paper is also related to a large volume of research on the economic impact of transportation infrastructure. Many economists have explored how transportation infrastructure affects regional economic growth (Duranton & Turner (2012), Banerjee et al. (2012), Faber (2014), Lin (2017)), inter-regional
2. Introduction

trade (Donaldson (forthcoming), Duranton et al. (2014), Allen & Arkolakis (2017)), labor market (Michaels, 2008), manufacturing activity (Ghani et al., 2016), urban formation and development (Baum-Snow (2007), Baum-Snow et al. (forthcoming), Nagy (2017)), among others. We take a novel angle by examining the effect of highway networks on the geographic distribution of firm productivity and production, highlighting the market access dynamics in general equilibrium.

Very closely related to this paper, in terms of the “market access” approach, are Donaldson & Hornbeck (2016) and Baum-Snow et al. (2017). Since both papers examine macro-level outcomes of local economies like total land value and GDP growth, for simplicity, they only specify one traded sector and one type of market access for each location, and find that better market access improves macro-level outcomes. Looking at the distribution of individual firms’ productivity, this paper considers multiple industries with heterogeneous firms and the counteracting effects of two types of market access. Although a decrease in trade cost enhances both CMA and FMA for a location, the total local firm revenue will not increase if import competition dominates export access. This can be the case, as an example, when location o is better connected to location d with many productive firms in industry j but few firms in other industries (so d’s total income/expenditure is small), and thus firms in j – d exert strong competitive pressure on firms in j – o, but d offers a tiny export market for firms in j – o. As the geographic distribution of firms varies by industry, so will the overall effect of trade cost shocks on a given location. While both papers focus on reduced-form evidence, this paper estimates a fully specified structural model using detailed firm-level data and recovers counterfactuals related to trade cost shocks. In particular, we highlight how changes in location o’s market access can influence the market access of other locations, and changes in other locations’ market access can in return affect o’s market access.

The rest of this paper proceeds as follows. Section 2 briefly introduces the empirical setting, and establishes two sets of stylized facts in order to motivate our model in Section 3. Section 4 describes how to measure historical road travel time between prefectures and link it to trade cost. Section 5 estimates the structural model and shows how well the model fits the data. Section 6 conducts reduced-form tests of the models key predictions, together with robustness checks and discussion of alternative hypotheses. Section 7 uses the model to recover counterfactual scenarios related to trade cost changes. Section 8 concludes.

---

3 This approach, as we will elaborate in Sec.3, captures the direct and indirect effects of trade cost changes in general equilibrium, not just the direct effects in partial equilibrium as in most earlier papers.

4 As we will show in Sec.3.2, the two types of market access, CMA and FMA, are proportional in a one-sector setting.
2 Empirical Patterns: Geographic Distribution of Firm Productivity and Production

In this section, we briefly introduce our empirical setting, and establish two stylized facts about the geographic distribution of firm productivity and production. First, a firm’s location explains a significant fraction of the substantial variation in productivity, and the fraction of variation explained depends on the industry in question. Second, the degree of firms’ geographic agglomeration also varies dramatically by industry. These results point to the importance of understanding the distribution of firm productivity and production in an economy from a geographic perspective, with particular attention to industry-specific patterns, and motivate subsequent work on how productivity and production distributions are affected by trade costs that separate geographic locations.

2.1 Empirical Setting: Chinese Industrial Firms Database

Detailed firm-level data, based on which we calculate individual firms productivity, come from the Chinese Industrial Firms Database (CIFD). An annual firm-level survey conducted by China’s National Bureau of Statistics, the database covers mining, manufacturing, and public utility industries. In this paper, we will focus on manufacturing firms, and the decade between 1998 and 2007 in which the surveys contain necessary variables for standard productivity measurements.

Firms present in this dataset are relatively large. According to the official documentation, the surveys include all state-owned enterprises (SOEs), and non-state firms with sales greater than 5 million CNY (“above-scale” firms). Yet in fact, a significant number of below-5-million non-state firms, accounting for about 5% of the unbalanced panel, are also included. In comparison with the 2004 Economic Census that covers the universe of firms, the CIFD excludes 80% of firms, yet these “below-scale” firms only accounted for 28.8% of industrial workforce, 9.9% of output, and 2.5% of exports (Brandt et al., 2012). Appendix A.(1.1.1) provides details about this database and how the final sample is constructed.

Table 1(A) provides key summary statistics from firm balance sheets. From 1998 to 2007, aggregate real industrial output experienced an impressive 4-fold increase, value added and export increased by even more, while total employment grew by 40%, suggesting considerable productivity.

---

6 Thus in this paper, the entry and exit of very small non-state firms are about when they first appear in and disappear from the CIFD. We discuss how this will affect our results in Sec.6.3.
2.2 Geographic Location and Productivity Dispersion

Gains. Though the total number of firms more than doubled from 129k to 288k, there was massive
entry and exit simultaneously, as shown in Table 1(B). Approximately 10 – 15% of firms enter and
exit every year, and only 30k firms remained throughout the sample period.

Table 1(C) summarizes firm productivity distributions across industries. For each of the 29
2-digit industries, we calculate the Levinsohn-Petrin output productivity for individual firms. The
well documented firm heterogeneity is confirmed: if we rank firms by their productivity in a year,
firms at the 90th percentile are about 0.7 log points, or 100% more productive than firms at the
10th percentile. The 1998-2007 decade saw a substantial increase in aggregate productivity level,
and a slight decline in productivity dispersion. Productivity dispersion quantified using value-
added productivity measures like Olley-Pakes and Ackerberg-Caves-Frazer is an order of magnitude
greater, echoing findings in Gandhi et al. (2016), but the overall rise in aggregate productivity and
decline in productivity dispersion remain.

2.2 Geographic Location and Productivity Dispersion

We now show that a firm’s geographic location explains a significant fraction of between-firm
productivity dispersion. If we assume that a prefecture’s contribution to local firms’ productivity is
the same across industries, then where firms are located accounts for about 2 – 3% of the variation
in firm productivity (Table 2). This is already a sizable fraction in comparison with other common
factors, such as ownership type (state-owned, private, etc.) and firm age, which explain less than
0.1%. Yet the effect of geographic locations likely varies by industry: while Boston can be a good
fit for pharmaceutical firms, it does not seem an ideal environment for oil refineries. Allowing the
effect of geographic locations to vary by industry boosts the fraction of variation explained by 5
times to 12 – 14% (Table 2). One may think of the first 2 – 3% of the variation explained as the
common contribution of geographic locations to firm productivity, and the next 10 – 11% as the
industry-specific contribution. For example, a well-educated labor pool in a city supports local
firms regardless of industry, yet industries that demand more skilled labor likely benefit more.

While geography seems to matter for firm productivity overall, Figure 1(A) documents that
the importance of geography varies across industries. In 2006, the fraction of variance explained by
firms’ geographic locations ranges from less than 2% for industries like oil refining and coking to
more than 20% for industries like ferrous metal smelting and rolling.
2.2.1 Geographic Agglomeration of Firms

Our second empirical pattern is about how firm production is distributed geographically. While we have documented that geography matters for firm productivity across industries, firms do not always agglomerate in highly productive locations. Figure 1(B) shows the Ellison-Glaeser agglomeration index for the 29 2-digit industries. Recall that, when Ellison & Glaeser (1997) introduce this index to the 1987 U.S. Census of Manufactures data, the authors designate an industry with an index value above 0.05 as “highly agglomerated”, and an industry with a negative index value as the opposite. Overall, Chinese manufacturing firms in 2006 were not highly agglomerated, with an average index of 0.017 across industries. Again, industry heterogeneity is evident: the index ranges from negative for industries like tobacco products to above 0.06 for industries like electronic equipment. Together, results in this section invite questions about what determines the distribution of firm productivity and production across space.

3 Theoretical Framework

To understand the geographic patterns about firm productivity and production distributions, we further develop the “market access” approach per Donaldson & Hornbeck (2016) in a Melitz (2003) framework of firm heterogeneity and trade. As inter-location trade costs decline, firms in a location face more import competition on the one hand, but also have greater export access on the other. We derive expressions of consumer market access (CMA) to capture import competition, and firm market access (FMA) to capture export access. Both types of market access shapes the geographic distribution of firm productivity and production via firm selection: for a location, higher CMA, or more intense import competition, only allows the more productive firms to survive, raising local average productivity and shrinking the output of every surviving firm; higher FMA, or greater markets for export, works in the opposite direction.

The general equilibrium effect of trade cost changes becomes particularly salient in our setting and necessitates the “market access” approach. Many papers on the effect of transportation infrastructure strives to identify the partial equilibrium effect of trade cost shocks. For this purpose, the ideal experiment is to randomly assign highway connection, and compare locations that get connected with those that do not. However, in a network of locations, each location is affected by

\footnote{Both the percent of variation explained by prefecture and the agglomeration index have much higher averages and greater dispersion at 4-digit industry level (about 420 4-digit industries), see Glaeser & Xiong (2017).}
3. 3.1 Setup

We adopt the Melitz (2003) framework, derive explicit expressions of CMA and FMA, and show their respective implications for local firm productivity and production distributions. We begin by outlining the setup. ⁸

3.1 Notations

Representative consumers’ preferences are defined over the consumption of goods produced by J industries indexed by j, k ∈ {0, 1, 2, ..., J}. Industry j = 0 produces a homogeneous good. Each industry j ≥ 1 has a continuum of horizontally differentiated varieties, and each firm produces one of the varieties. There are N locations indexed by o (origin) or d (destination) ∈ {1, 2, ..., N}, and a symmetric iceberg trade cost τ od between o and d.

In industry j and location o, the unit cost of production (or composite input price) is c jo, and there is an underlying distribution of firm productivity G jo(ϕ) and potential mass of firms S jo. The mass of firms that produce (and we observe in data) is a fraction h jo of S jo. Individual firms are indexed by ω ∈ Ω jo, with each firm’s productivity draw ϕ joω.

---

⁸ Readers interested in the details of the Melitz setup may refer to Melitz & Redding (2014).
3.1.2 Preferences

Representative consumers have Cobb-Douglas upper-tier utility over industries,

\[ U = \sum_j \beta_j \ln Q_j, \quad \sum_j \beta_j = 1, \beta_j \in (0, 1) \]

In location \( o \), total expenditure on industry \( j \)'s good is thus \( X_{jo} = \beta_j I_o \), where \( I_o \) denotes the total income of \( o \).

Within each differentiated industry \( j \geq 1 \), the aggregator over these varieties takes the Constant Elasticity of Substitution (CES) form:

\[ Q_j = \left[ \int_{\omega \in \Omega_j} q(\omega)^{(\sigma_j-1)/\sigma_j} d\omega \right]^{\sigma_j/(\sigma_j-1)} \]

where \( \sigma_j > 1 \) denotes the within-industry CES elasticity.

The price index of industry \( j \)'s good is then

\[ P_j = \left[ \int_{\omega \in \Omega_j} p(\omega)^{1-\sigma_j} d\omega \right]^{1/(1-\sigma_j)} \]

3.1.3 Production and Pricing

Industry \( j = 0 \) produces a homogeneous good with a unit input, and the price of this homogeneous good is chosen as the numeraire. In industry-location \( j - o \), a potential entrant firm can pay fixed cost \( c_{jo} e_{jo} \) for a productivity draw \( \varphi_{jow} \), and can then choose to produce at unit cost \( c_{jo} / \varphi_{jow} \) (so production features constant returns to scale). A firm will only start producing if it expects the revenue to at least cover the fixed cost of production \( c_{jo} f_{jo} \).

Under CES demand and monopolistic competition, firms charge a constant mark-up \( \frac{\sigma_j}{\sigma_j - 1} \) above their unit cost of production. Given the trade cost \( \tau_{od} \) between locations \( o \) and \( d \), the price of firm \( j \omega \)'s product in location \( d \) is

\[ p_{j,od}(\varphi_{jow}) = \frac{\sigma_j}{\sigma_j - 1} \frac{c_{jo}}{\varphi_{jow} \tau_{od}} \]
3.2 Market Access

As we will characterize equilibrium in an industry, we now drop the industry subscript $j$ to streamline notation.

While the Melitz model specifies a fixed cost of export for each pair of locations, we make a key simplifying assumption: inter-location trade is only subject to iceberg trade cost, not fixed cost of export. In other words, as long as a firm chooses to produce, it sells its variety to all locations in the economy. This assumption allows us to derive clean expressions for market access measures, and is less stringent in intra-national trade, as in our empirical setting, than in international trade. In addition, since our data do not cover the “export” (selling to other prefectures in China) status of individual firms, it is quite challenging to estimate the fixed cost of export as many papers on international trade do.

3.2.1 Firm Market Access (FMA)

A destination $d$’s demand for the variety produced by a firm with productivity $\varphi$ in origin $o$ is

$$ r_{od}(\varphi) = q_{od}(\varphi)p_{od}(\varphi) = \frac{X_d}{P_d^{1-\sigma}} p_{od}(\varphi)^{1-\sigma} $$

$$ = \left( \frac{\sigma}{\sigma - 1} \right)^{1-\sigma} \tau_{od}^{1-\sigma} \frac{X_d}{P_d^{1-\sigma}} \left( \frac{c_o}{\varphi} \right)^{1-\sigma} $$

Total demand is the sum of demand over all destinations,

$$ r_o(\varphi) = \left( \frac{c_o}{\varphi} \right)^{1-\sigma} FMA_o $$

(1)

where

$$ FMA_o = \left( \frac{\sigma}{\sigma - 1} \right)^{1-\sigma} \sum_d \tau_{od}^{1-\sigma} \frac{X_d}{P_d^{1-\sigma}} $$

A location has high FMA, or access to a large market, if (1) it is well connected to other locations, which shows up as small trade costs $\tau$; (2) other locations have high demand, which shows up as large total expenditure $X$; (3) other locations have low levels of competition, which shows up as a high price level $P$). Intuitively, even if a location spends a large amount on an industry’s products, there will be little room for firms elsewhere if the local market is already highly competitive, or equivalently, at a low price level. FMA thus captures the aggregate size of markets that a local firm
can potentially reach.

It quickly follows that total demand/revenue for all firms in a location is

\[ R_o(\varphi) = S_o \int \left( \frac{c_o}{\varphi} \right)^{1-\sigma} FMA_d G_o(\varphi) \] (2)

### 3.2.2 Consumer Market Access (CMA)

The price index in each destination \( d \) is a CES aggregate of the prices of individual firms’ varieties that sell in \( d \). Competition among rival firms lowers the price index and enhances local consumers’ welfare. We thus relate a location’s price index to its consumer market access (CMA), \( P_{d}^{1-\sigma} \)

\[
P_{d}^{1-\sigma} = \sum_{o} \left[ M_o \int p_{od}(\varphi)^{1-\sigma} dG_o(\varphi) \right]
\]

\[
= \sum_{o} \left[ M_o \int \left( \frac{\sigma}{\sigma - 1} \frac{c_o \tau_{od}}{\varphi} \right)^{1-\sigma} dG_o(\varphi) \right] \equiv CMA_d
\]

Eq.(1) gives \( \left( \frac{c_o}{\varphi} \right)^{1-\sigma} = \frac{r_o(\varphi)}{FMA_o} \). Substituting this into the \( P_d - CMA \) equation above, and making use of Eq.(2), we obtain

\[
CMA_d = \left( \frac{\sigma}{\sigma - 1} \right)^{1-\sigma} \sum_{o} \tau_{od}^{1-\sigma} \frac{R_o}{FMA_o}
\] (3)

A location has higher CMA, or more competition, if (1) it is better connected to other locations, which shows up as smaller trade cost \( \tau \); (2) other locations have large competing firms, which shows up as larger total revenue \( R \); (3) firms in other locations can only reach a small market, which shows up as smaller \( FMA \). Intuitively, if a location has many large firms, but at the same time sells to a very large market, the competitive pressure that local firms exert on firms elsewhere will be lower.

Symmetrically, since \( P_{d}^{1-\sigma} \equiv CMA_d \), we write FMA as

\[
FMA_o = \left( \frac{\sigma}{\sigma - 1} \right)^{1-\sigma} \sum_{d} \tau_{od}^{1-\sigma} \frac{X_d}{CMA_d}
\] (4)

\(^9\)To the extent that firms in an industry use the output of all industries as intermediate input, and that the price of intermediate input is part of the composite cost of production, a location \( o \)'s higher CMA, or lower price index, of industry \( j \) will lower the cost of production \( c_{k,o} \) for all industry \( k \)'s. We formalize this in Appendix A.1.2 and derive input market access (IMA) based on CMA.
Eq.(3) and (4) illustrate that, if total revenue $R_{jo}$ is proportional to total expenditure $X_{jo}$ across industry-location’s, so is CMA to FMA. This is the case if there is only one traded sector, as in several previous papers on market access like Donaldson & Hornbeck (2016) and Baum-Snow et al. (2017). In our setting, CMA and FMA differ from each other because of the uneven distribution of production across locations.

Empirically, it is difficult to measure CMA as a recursive index. Again using $\left(\frac{\omega}{\varphi}\right)^{1-\sigma} = \frac{r_o(\varphi)}{FMA_o}$, we express CMA in unit cost of production,

$$CMA_d = \left(\frac{\sigma}{\sigma - 1}\right)^{1-\sigma} \sum_o \tau_{od}^{1-\sigma} \left(\sum_{\omega \in \Omega_o} \left(\frac{\varphi_{o\omega}}{c_o}\right)^{\sigma-1}\right) \quad (5)$$

Clearly, a location has high CMA if it is well connected to locations that have many productive firms (large sum of high $\varphi$ firms).

### 3.3 Local Productivity Distribution

In location $o$, a firm at the local productivity cutoff $\varphi_o^*$ makes just enough profit $\pi(\varphi_o^*)$ to offset the fixed cost of production $c_o f_o$, Eq.(1) implies

$$\pi(\varphi_o^*) = \frac{r_o(\varphi_o^*)}{\sigma} - c_o f_o = 0$$

$$\Rightarrow (\varphi_o^*)^{\sigma-1} = \left(c_o\right)^{\sigma} f_o \Rightarrow \varphi_o^* \propto (FMA_o)^{\frac{1}{1-\sigma}} \quad (6)$$

Ceteris paribus, an increase in FMA lowers the cutoff $\varphi_o^*$: a larger market size allows local firms to spread their fixed costs of production over more product units, and hence unproductive firms can manage to enter or survive. By Eq.(4), FMA is decreasing in CMA, so an increase in CMA raises the cutoff $\varphi_o^*$: more competition makes it more difficult for unproductive firms to enter or survive. Similarly, by Eq.(1), local individual firms’ revenue and total revenue of a location both increase in the location’s FMA and decrease in its CMA. \(^{11}\)

Assume an underlying Pareto local productivity distribution with scale and shape parameters

\(^{10}\)An extreme case: each industry-location maintains trade balance, i.e. $R_{jo} = X_{jo}$.

\(^{11}\)One can see this more clearly by dividing a location’s FMA into that due to its home market and that due to its export market (selling to other locations),

$$FMA_o = FMA_{o, \text{ex}} + \left(\frac{\sigma}{\sigma - 1}\right)^{1-\sigma} \frac{X_o}{CMA_o}$$
\((\varphi, \theta)\), so the probability density function \(g(\varphi_\omega) = \frac{\theta_o(\varphi_o)^{\theta_o}}{(\varphi_o)^{\theta_o+1}}\). Changes in CMA or FMA move \(\varphi_o^* \geq \varphi\) around, but the lower-truncated Pareto distribution is still Pareto, with scale parameter \(\varphi_o^*\) and the same shape parameter \(\theta_o\). For \(\theta_o > 1\), \(\theta_o\) the cutoff pins down the mean productivity of surviving firms,

\[
\varphi_o = \frac{\theta_o \varphi_o^*}{\theta_o - 1} = \frac{\theta_o}{\theta_o - 1} \left( \frac{(c_o)^{\sigma} f_o}{FMA_o} \right)^{\frac{1}{\sigma}}
\]  

(7)

All firms pay a fixed cost of entry \(c_o e_o\) to draw from the underlying productivity distribution \(G_o(\varphi)\), but only those who get a draw above the cutoff \(\varphi_o^*\) produce. Free-entry condition imposes that the expected ex-ante profit of firms that produce just offsets the fixed cost of entry,

\[
\int_0^\infty \pi(\varphi) dG_o(\varphi) = \int_{\varphi_o^*}^\infty \left( \frac{r(\varphi)}{\sigma} - c_o f_o \right) dG_o(\varphi) = c_o e_o
\]

\[
\Rightarrow \frac{R_o}{\sigma} = h_o S_o c_o f_o + c_o e_o S_o
\]  

(8)

where \(h_o = \int_{\varphi_o^*}^\infty dG_o(\varphi)\) denotes the share of underlying firms that enter and produce, and thus \(h_o S_o\) the observed mass of firms. For simplicity, we write \(e_o S_o = E_o\). Under this free-entry condition, lowering barriers to entry in a location attracts more entrants there, intensifies local competition, and pushes down the local price level in equilibrium.

4 Trade Cost Measurement

Having derived explicit expressions of various market access, we proceed to the corresponding empirical measurement. A key missing piece in our setting is the trade cost between prefectures in China. Without inter-prefecture trade data, in particular data on spatial price gaps, \(^{13}\) we are unable to directly estimate trade cost, and hence follow an indirect route in the economic geography literature to infer trade cost from road travel time between prefectures. \(^{14}\)

\(^{12}\) For \(\theta_o \in (0, 1]\), the mean approaches infinity.

\(^{13}\) See Atkin & Donaldson (2015) for a recent advance in using spatial price gaps to identify intra-national trade costs. The authors also review a voluminous literature along this line.

\(^{14}\) In Appendix A.1.3, we discuss why we focus on road transport rather than other modes of transport, like railway, air, and waterway.
4.1 National Highway Construction

Since the early 1990s, and in particular during our sample period from 1998 to 2007, China went through massive expansion of highway networks. In 1990, there were essentially no limited access highways between Chinese prefectures. Existing inter-city roads had at most two lanes with unrestricted access, and were often unpaved. Thus, Baum-Snow et al. (2017) assume merely 25 km/h for inter-prefecture traveling on local roads. Roads took care of less than 5% of freight ton-km’s, and almost all goods were moved by railway or waterway.

In 1992 under the National Trunk Highway Development Program, the Chinese State Council approved the blueprint of the “5-7” system, which refers to 5 North-South vertical and 7 East-West horizontal axes World Bank (2007). The project aimed to connect all provincial capitals and cities with an urban registered population above half a million on a single highway network, and to connect targeted regional centers and the national border in border provinces as part of the Asian Highway Network. The Chinese Ministry of Communications (predecessor to the current Ministry of Transport) set 1992-1997 as the “kick-off” phase in which only a handful of highways were completed, and 1998-2007 as the “rapid development” phase in which large-scale construction took place. Originally earmarked for completion by 2020, this nationwide construction endeavor concluded ahead of schedule by the end of 2007, in large part due to the government’s stimulus spending in response to the 1997 Asian Financial Crisis Asian Development Bank (2007). In consequence, from 1998 to 2007, China’s total highway length grew from 8.7k km to 53.6k km. By 2010, highways and roads carried over 30% of freight ton-km’s. Given the post-1998 acceleration of construction, the State Council approved an even more ambitious follow-up plan in Dec. 2004. The stated purpose of this “7-9-18” system was to bring highway connection to all cities with an urban registered population above 200k by 2020.

Prior to the advent of national trunk highways, national highways and provincial highways served as the main routes between prefectures, usually subject to a speed limit of 80 – 100 km/h and 70 km/h, respectively. However, many prefectures were not on existing national highways. Moreover, due to poor road quality and frequent congestion, the actual speed on these highways was often far below the limit. In contrast, newly built as 4-lane limited access tollways, the national

---

15 This subsection that tells the history of China’s national highway system borrows heavily from Sec.2.1 of Faber (2014) and Sec.2 of Baum-Snow et al. (2017).
17 “7-9-18” refers to 7 radial axes from the capital Beijing, 9 vertical axes, and 18 horizontal ones. In 2013, the Ministry of Transport added two additional vertical axes, aiming to having in total 118k km of highways by 2030.
trunk highways commonly feature a speed limit of 110 – 120 km/h, and run in parallel with existing major roads in many areas.

### 4.2 Road Travel Time and Trade Cost

We make use of 2 data sources to estimate by how much highway construction reduces inter-prefecture road travel time. First, the ACASIAN GIS data, which we describe in Appendix A.(1.1.2), provide historical maps of highway networks in China, allowing us to hand-collect in which year each prefecture received highway connection. If unclear based on maps, we supplement the data with news search on highway construction. As Figure 2 shows, while there were only sparse regional highways in 1998, the vast majority of prefectures in China had been connected by highways in an integrated national network by 2007.

Second, working with Google Maps APIs, we obtain contemporary (Nov. 2016, when this task was completed) travel distance and time matrices. Since very few, if any, prefectures are still off the national highway network, the normal travel time is almost completely based on highway travel, i.e. one spends the least time traveling between prefectures by staying on highways all the time. Recall that very few prefectures, typically the remote ones with little manufacturing activity, were still left behind during the highway boom by 2007, so the contemporary normal travel time provides a good proxy for the 2007 travel time. If we specify “avoid highways”, Google Maps will avoid highways altogether when choosing routes between prefectures, typically staying on national and provincial major roads that were already in place in 1998. This usually results in minimal changes in travel distance, but doubles travel time.

Since Google Maps can’t recover 1998-2007 travel time, we use the historical highway maps and contemporary travel time in 3 steps, incorporating two main adjustments.

1. For an origin location \( o \) and destination \( d \) in year \( y \), if the highway map of year \( y \) shows that both \( o \) and \( d \) were connected to highways, then we use the normal travel time; otherwise, use the “avoid highways” time.

2. “Block” adjustment. The first step probably underestimates the actual travel time in the early years of our sample period. As shown in Figure 2, in the late 1990s, there were several regional “blocks” in which highways connected regional centers and nearby cities, but sometimes no highways between different blocks. When \( o \) and \( d \) belong to different blocks, one can’t always stay on highways when going from \( o \) to \( d \). Therefore, for each year, we identify a few highway
blocks, and only use normal travel time if $o$ and $d$ are connected via the same block of highways. The number of blocks declined as the highway networks expanded over time, and by 2007, basically all prefectures lay on one nationwide highway block.

3. “Detour” or “fastest path” adjustment. Especially when $o$ and $d$ are far apart, the “avoid highways” travel time will likely exceed the actual travel time even if neither prefecture is directly connected to highway networks, since one may still go on highways between the two whenever available. We thus allow one to take “detours” between $o$ and $d$ as long as this reduces travel time.

- Let $t_{od}$ denote travel time between $o$ and $d$. Given a 3rd prefecture $m$, record $(t_{om} + t_{md})$.
- For all prefectures other than $o$ and $d$, if $t_{od} > \min_m\{t_{om} + t_{md}\}$, replace $t_{od}$ with $\min_m\{t_{om} + t_{md}\}$. Clearly, this is only possible if at least one of $t_{om}$ and $t_{md}$ is normal travel time.
- Iterate the above two steps until $t_{od}$ doesn’t get smaller.

After these adjustments, Table 3 shows the reduction in travel time as a result of the nationwide highway expansion. In our sample period 1998-2007, there were 337 prefectures in China. We restrict our empirical analysis to 287 prefecture-level “cities” and leave out 50 prefecture-level “regions” that were mostly remote, underdeveloped areas in Western China with little manufacturing activity. Among all $\binom{287}{2} = 41041$ prefecture pairs, while the average travel distance stayed more or less the same, the average travel time decreased by over 40% from 1998 to 2007.

We then follow a widely used approach in economic geography to relate travel time to trade cost. Baum-Snow et al. (2017) specify the following formula to relate road travel time to trade cost,

$$\tau_{od} = 1 + 0.004\rho (\text{travel time}_{od})^\lambda$$

where $\rho > 0$ and $\lambda \in (0, 1)$ (9)

and use $\rho \in [0.5, 2]$, travel time in hours, and $\lambda = 0.8$ to incorporate some concavity. These parameter values correspond to a modest ad-valorem tariff of $1.6 - 3.1\%$ per day (24 hours) of travel time, consistent with estimates in Limao & Venables (2001) and Hummels & Schaur (2013). However, this relationship likely varies across industries based on, say, the per-unit-value cost of transport. For instance, high weight-to-value industries such as timber and coking likely have a larger $\rho$. We thus empirically estimate this relationship between travel time and trade cost.

---

18 The number slightly changed over time, due to creation of new prefectures and merger of old ones.
5 Structural Estimation and Model Fit

The structural model in Sec.(3) and trade cost in Sec.(4) pave the way for estimation of the model. This section estimates key parameters of the model based on Sec.(3). With these parameters in hand, we test the model’s fit, and show that such a simple model provides a decent description of the actual geographic distribution of productivity and production.

5.1 Estimation

To focus on the two main forces (import competition vs. export access) in local firm selection, we make an additional assumption that significantly simplifies the structural estimation: the homogeneous good (in sector \( j = 0 \)) is produced in all locations with a unit cost and is costlessly traded. In such an incomplete specialization equilibrium, the unit cost of production is equal across all locations, \( c_{jo} = c_j \forall o \in \{1, 2 \ldots N\} \). While stringent, this assumption is in fact common in firm heterogeneity and trade literature, see Melitz & Redding (2014)) for an example. In Appendix A.1.2, we relax this assumption and point to an alternative method to measure market access empirically.

For the manufacturing sector (for which we have firm-level data), we also impose location-level trade balance on the income-expenditure relationship for each location. Under this assumption, although a location can spend more on an industry’s goods than it makes from selling this industry’s goods, a location’s total revenue from local firms in all industries is equal to its total expenditure on all industries’ goods, i.e. \( X_{jd} = \gamma_j \sum_j R_{jd} \). \( \gamma_j \) represents the representative consumers’ proportion of total income from manufacturing (traded sector) spent on industry \( j \)’s output, and we obtain \( \gamma_j \) from the 2002 national input-output matrix.

We now classify the model’s parameters into 3 categories: (1) taken from existing literature; (2) computed directly from data; (3) estimated by fitting simulated moments to actual moments in the data. To start with, we borrow from Broda & Weinstein (2006) and set the same CES elasticity for all 2-digit industries, i.e. \( \sigma_j = 4 \forall j \). 19

We now directly estimate two sets of parameters for each industry-location \( j - o \) from firm-level data. 20 First, as we assume a Pareto distribution of firm productivity in each \( j - o \), we follow

---

19 Without inter-prefecture trade data, we can’t directly estimate the CES elasticity as in Broda and Weinstein (2006). For robustness checks, we try different values of \( \sigma \in [3, 5] \). For an industry, a larger \( \sigma \) implies more intense competition between firms.

20 For this step, “location” refers to province, which typically contains 8 – 16 prefectures, so that there are sufficient firms in each industry-location and we obtain more robust estimates.
Gabaix and Ibragimov (2011) to recover the shape parameter. 21 In each year, within each \( j-o \), we rank firm productivity \( \varphi_{j_o\omega} \) in decreasing order, and estimate \( \theta_{j_o} \) in the following OLS regression, 22

\[
\ln \left( \text{rank}_{j_o\omega} - \frac{1}{2} \right) = \eta_{j_o} - \hat{\theta}_{j_o} \ln \varphi_{j_o\omega}
\]

Note that the standard error here on \( \theta_{j_o} \) is not the OLS s.e. Recall that we use Levinsohn-Petrin output productivity, based on an estimated industry-specific production function, in the main empirical specification. We also replicate our main results using alternative productivity measures including Olley-Pakes, Ackerberg-Caves-Frazer, and Gandhi-Navarro-Rivers in Appendix A. 22

Second, with the unbalanced panel data, for an industry-location \( j-o \) that has at least appeared twice (i.e. has \( \geq 1 \) firm for \( \geq 2 \) years, we rely on the free-entry condition Eq.(8) to solve for \( c_{j_o}f_{j_o} \) and \( c_{j_o}e_{j_o} \). 23 For example, observing total revenue \( R_{j_o} \) and mass (number) of firms \( S_{j_o} \) in years 1 and 2, we write (omitting \( j-o \) subscripts and use \( y \in \{1, 2\} \) to indicate years),

\[
\begin{cases}
\frac{R_1}{\sigma} = S_1cf + cE \\
\frac{R_2}{\sigma} = S_2cf + cE
\end{cases} \Rightarrow \begin{cases}
f = \frac{1}{c\sigma} \frac{R_2-R_1}{S_2-S_1} \\
E = \frac{R_1}{c\sigma} - S_1f
\end{cases}
\]

For industry-location’s that appear in \( T > 2 \) years, we pick \( \left( \frac{T}{2} \right) \) 2-year pairs, solve the system of equations above for each pair, and take the average for \( f \) and \( E \). 24

Now we specify the parameters to recover from structural estimation, conducted at industry-year level.

- Parameters used to convert travel time to trade cost, \( \rho_j \) and \( \lambda_j \) as in Eq.(9). As discussed, this time-cost relationship likely differs by industry.
- Given the importance of international trade for China in our sample period, particularly since China joined the WTO in 2001, it is necessary to incorporate the market access effects due

21 Alternatively, maximum likelihood gives the following estimates

\[
\hat{\varphi}_{j_o^*} = \min \{ \varphi_{j_o\omega} \} \text{ and } \hat{\theta}_{j_o} = \frac{1}{\text{Mean}[\ln \varphi_{j_o\omega}] - \ln \hat{\varphi}_{j_o}}
\]

This approach is quite sensitive to outliers of firm productivity.

22 Around 6.2% of estimated \( \theta \)'s are smaller than 1, often from industry-location’s with few firms. In this case, we replace the \( \theta \)'s with the national mean of the industry.

23 We ignore industry-location’s that has appeared only once in the sample period, which account for a tiny fraction of output. For instance, industry-prefecture’s that only appear in 2004 and not other years account for 0.7% of the total output in 2004.

24 About 7.4% of estimated \( f \)'s and 9.0% of \( E \)'s are negative, often from industry-location’s with few firms. In this case, we replace the \( f \)'s and \( E \)'s with the respective national mean of the industry.
to rest of the world (RoW). Without firm-level data from RoW, we assume a point-like RoW that all Chinese prefectures trade with, and use a prefecture’s travel time to the nearest port as its travel time to RoW.\footnote{9 ports that handle the largest volume of international trade in 2001 \citep{Baum-Snow2017}: Dalian, Qinhuangdao, Tianjin, Qingdao, Lianyungang, Shanghai, Ningbo, Guangzhou, and Shenzhen.} This gives us two additional parameters: CMA-adjusted total expenditure $X_{\text{CMA}}$ and FMA-adjusted total revenue $R_{\text{FMA}}$ for RoW.

Having specified all parameters, we proceed to structural estimation based on Sec.\,(3). For each industry and year, we estimate $\Psi_j = \{\rho, \lambda, (X_{\text{FMA}})_{\text{RoW}}, (R_{\text{CMA}})_{\text{RoW}}\}$ as follows.

1. Compute the inter-prefecture trade cost matrix, $T$.

2. Compute $\{\text{CMA}\}_j$ following Eq.\,(5). $\{\text{CMA}\}_j$ then gives $\{\text{FMA}\}_j$ by Eq.\,(4).\footnote{$\{\text{CMA}\}_j$ denotes the set of CMA’s (of every location) for industry $j$.}

3. $f_{\text{jo}}$ and $\text{FMA}_{\text{jo}}$ then gives $\varphi^*_{\text{jo}}$ by Eq.\,(6). Under the assumption of Pareto distribution of firm productivity in $j - o$, local mean productivity $\bar{\varphi}_{\text{jo}} = \frac{\theta_{\text{jo}}\bar{\varphi}^*_{\text{jo}}}{\theta_{\text{jo}}-1}$ (this requires $\theta_{\text{jo}} > 1$).

4. The true $\Psi_j = \{\rho, \lambda, (X_{\text{FMA}})_{\text{RoW}}, (R_{\text{CMA}})_{\text{RoW}}\}$ will meet the moment condition

$$E[y(\Psi_j)] = E[\bar{\varphi}(\Psi_j) - \bar{\varphi}] = 0$$

where $\bar{\varphi}$ indicates moments from simulated data. We thus seek $\tilde{\Psi}_j$ that achieves

$$\tilde{\Psi}_j = \arg \min_{\Psi_j} \{y(\Psi_j)'Wy(\Psi_j)\}$$

\hspace{1cm} (11)

where a location’s weight in the weighting matrix $W$ is proportional to its mass/number of firms.

We follow \citet{Eaton2011} to calculate standard errors by bootstrapping, taking into account both sampling error and simulation error.

### 5.2 Model Fit

This subsection summarizes parameter estimates from the previous subsection and presents evidence that this simple model fits well the actual geographic distribution of firm production. Figure 3(A) plots the estimated $\rho$, which relates travel time to trade cost, against weight-to-value ratios, across industries in 1998. Weight-to-value ratios, which measures the weight of an industry’s
output per unit value, serves as a proxy of the price of transportation per unit value. For industries that pay a higher price for transportation, a decrease of one day in travel time likely means a larger decrease in trade cost. Indeed, Figure 3(A) shows a strong positive correlation between the estimated $\rho$ and weight-to-value ratios. Since the weight-to-value ratios based on U.S. commodity flows may deviate from their counterpart in Chinese data, we also obtain the proportion of total expenses spent on road transport from the 2002 Chinese national input-output table, and conduct a similar exercise. As show in Figure 3(B) The strong positive correlation between $\rho$ and the share of road transport expenses remains.

With the estimated $\Psi$ in hand, we compute CMA following Eq.(5), then FMA by Eq.(4), and finally industry-location total revenue $R$ by Eq.(2). Since we do not target $\{R\}$ when searching for $\Psi$ that satisfies the key moment condition (11), comparing the model-simulated $\{\hat{R}\}$ with the actual $\{R\}$ in data will shed light on how well the model fits the geographic distribution of production. Figure 4 plots the simulated $\{\hat{R}\}$ against the actual (both in natural logs), based on 1998 firm-level data (first year in our sample period). The simulated $\{\hat{R}\}$ match with the actual quite well, with a slope almost equal to 1 and quite a small and insignificant constant term. The match becomes worse (1) at the very high end, due to a small number of extremely large outliers in firm productivity distribution; (2) at the low end, probably since the assumed Pareto distribution of firm productivity typically features a higher density than actual at the low end, but better approximates the actual distribution as one moves toward the high end.

Table 4 shows similar patterns about the actual vs. simulated geographic distribution of firm production, also based on 1998 data. In Panel A, within each of the 29 2-digit industries, we rank prefectures that have firms in this industry by total revenue, and examine the prefectures in different size groups (Top 10 vs. Bottom 40). Again, our model well matches the actual data in this respect: for an industry, the 10 prefectures with the most revenue in data are almost always (97.3% of the time) also among the Top 10 according to the model. This mean decreases to 83.5%, with a greater standard deviation, when it comes to the Bottom 40 prefectures. Panel B shows a similar story about the geographic concentration of firm production. Again across industries, the share of revenue accounted for by the Top 5 and 10 prefectures are almost identical between simulated

---

27 Industry-level weight-to-value ratios, in 1k U.S. dollars per metric ton, come from 2007 U.S. Commodity Flow Surveys. See Duranton et al. (2014) for details. We can only match 22 of 29 2-digit industries in CIFD to sectors in CFS.

28 Note that, if an industry spends a large fraction of total expenses on road transport, it can mean either a high price of transport per unit value (e.g. heavy output), or a large quantity of transport services used (e.g. producers are often far away from consumers.
and actual data. Nonetheless, the match deteriorates toward the low end for Bottom 20 and 40 prefectures, but the bottom prefectures typically accounted for less than 0.5% of the total revenue of an industry. Hence we feel confident that our simple model does a decent job approximating the geographic distribution of the bulk of firm production, and will generate meaningful counterfactuals when we estimate the general equilibrium effect of highway expansion in Sec.7.

6 Reduced-Form Evidence

This section reports reduced-form evidence about how a location’s market access affects local firm productivity and production. To the extent that the evidence supports the theoretical predictions in Sec.3, this section provides further confidence in the model’s fit.

Before presenting regressions, we note that a location’s productivity distribution and production are co-determined in equilibrium together with its market access, generating endogeneity bias if we simply regress local productivity and production outcomes on market access measures. Thus for regressions in this section, we exclude each industry-location $j-o$’s own contribution, $(\frac{X}{FMA})_{jo}$ and $(\frac{R}{CMA})_{jo}$, respectively from its CMA and FMA (recall Eq.(3) and (4)). These terms are usually so small that this adjustment hardly affects our main results. Still, because changes in one location’s market access will simultaneously induce changes in other locations’ market access, the point estimates on market access measures do not identify an average treatment effect, but rather empirically characterize the relationship between market access and outcomes of interest in equilibrium.

Table 5 presents summary statistics at industry-prefecture-year level. Firm productivity and production outcomes, such as mean productivity, number of firms, total revenue, etc., all increased dramatically from 1998 to 2007, so did CMA. The increase in FMA is relatively modest, due to the considerable increase in CMA and a smaller increase in expenditure (recall Eq.(4)).

6.1 Market Access and Industry-Location Mean Productivity

We first examine how market access affects productivity distribution at industry-location level. Recall that Eq.(6) predicts that local productivity cutoff increases in CMA but decreases in FMA. Since the minimum productivity in an industry-location is measured with much noise (extreme outliers are common), we investigate the empirical relationship between market access and local
mean productivity using the following regression,

$$\tilde{\varphi}_{jot} = b_1 \text{CMA}_{jot} + b_2 \text{FMA}_{jot} + \epsilon_{jot}$$

(12)

where $$\tilde{\varphi}_{jot}$$ is the mean productivity in industry-prefecture-year $$j - o - t$$, and all variables are in natural logs. We include industry*prefecture and industry*year fixed effects, and cluster standard errors at prefecture level. Table 6(A) present the results. In Column (1), we use the basic definition of CMA and FMA based on Eq.(5) and (4). Conditional on FMA, CMA exhibits a strong positive correlation with local average productivity, with an increase of 1 standard deviation (s.d.) in CMA corresponding to about 0.24 s.d increase in local mean productivity. In contrast, conditional on CMA, an increase of 1 s.d. in FMA is associated with 0.18 s.d. decrease in local mean productivity. Figures 4(A) and 4(B) show these empirical patterns visually. Column (2) replicates Column (1), but uses output-weighted mean productivity as the dependent variable. This puts higher weight on productive firms, due to the strong positive correlation between firm productivity and size. The empirical patterns in Column (1) remain in Column (2).

A key endogeneity concern is that local economic shocks might have affected both market access and firm productivity and production, for instance, if prefectures with promising prospects for industrial growth were given priority to receive highway connection. We first show that, in our sample period, a prefecture’s industrial growth in total industrial output, value added, employment, ... does not predict when it was connected to highway networks (see Appendix A, ??). We then develop two alternative measures of market access: (1) “distant neighbor”, which excludes prefectures within 300km of travel distance from the prefecture in question, is less likely to be correlated with local economic conditions; (2) “baseline mass”, which uses contemporary travel time but sticks with baseline (1998) economic mass (firm productivity, output, etc.), alleviates the bias due to the endogenous response of local economic mass to changes in trade costs. In Table 6(A), Columns (3)-(6) replicate Columns (1)-(2), but use the two alternative measures of market access, and the strong correlations between local mean productivity and market access are insensitive to alternative measures. Note that, since economic mass and market access are determined jointly in equilibrium involving all locations in the network, these alternative measures are not theoretically founded, and merely serve as robustness checks.

Following Table 6(A), Table 6(B) explores heterogeneous effect of market access across industries that rely more or less on road transportation. We categorize the 29 2-digit industries into
tertiles based on the share of road transport expenses in total input, and repeat Column (1) of Table 6(A) on these 3 subsamples. From Column (1) to (3), the correlations between local mean productivity and market access become stronger and more significant as the share of road transport expenses rises.

6.2 Market Access and Individual Firm Production

Next, we test Eq.(1) that predicts a positive correlation between an industry-location’s FMA and a local individual firm’s revenue, conditional on the firm’s productivity. The regression specification resembles Eq.(12), but the dependent variable is now individual firm revenue, and we control for individual firm productivity on the RHS. Column (1) in Table 7(A) starts by confirming the well-established positive correlation between firm productivity and size. Remarkably, controlling for a firm’s own productivity, its industry-prefecture’s market access still strongly affects its revenue. Specifically, 1 s.d. increase in FMA corresponds to 0.32 s.d. increase in firm revenue. Columns (2) and (3) show that these patterns persist if we use alternative market access measures.

As discussed in Sec.3, a decline in trade costs results in competing effects on individual firm’s output: import competition compresses firm output, while export access works against import competition. Which effect dominates likely depends on a firm’s productivity: productive firms will benefit more from a larger export market than losing from more intense competition, and the other way round for unproductive firms. Following Table 7(A), Table 7(B) shows that, conditional on firm productivity, the positive correlation between FMA and firm revenue becomes stronger and more significant as firm productivity rises from Column (1) to (3).

6.3 Market Access and Firm Entry & Exit

We proceed to the entry & exit dynamics associated with market access, presenting results in Table 8. Our firm selection mechanism entails that higher CMA makes unproductive firms more likely to exit, while higher FMA makes it easier for them to stay. Columns (1)-(3) test this hypothesis. Given two years, we set the earlier one (2004 here) as baseline, the later one (2007 here) as endline, and define “firm exit” as an indicator of a firm being present at baseline but not at endline. We take the long difference between baseline and endline for market access measures, and categorize firms at baseline into tertiles based on a firm’s productivity ranking within its industry.
It is clear that market access affects exit decisions mostly among the less productive firms. Column (1) shows that a 1% increase in CMA is related to an increase of 2.1 percentage points, while a 1% increase in FMA to a decrease of 1.8 percentage points, in the exit probability of the less productive firms. This pattern diminishes as firm productivity rises in Columns (2) and (3).

Column (4) evidences the prediction that higher CMA deters, while higher FMA encourages, firm entry. We tag a firm as “entrant” if it is present at endline but not at baseline, and count the number of entrants at industry-prefecture level. As in Column (4), a 1% increase in CMA is related to an 0.62% fewer, while a 1% increase in FMA to 0.41% more, entrants. The evidence on firm entry and exit suggests that market access works through firm selection.

Since the CIFD excludes very small non-state firms, this paper misses the very low end of the national productivity distribution (given the strong correlation between firm productivity and size). Still, such firms account for a tiny fraction of aggregate output and export (recall Sec. ??). Even without such firms, the import competition and export excess forces, captured by CMA and FMA respectively, are theoretically relevant and empirically present in the CIFD sample, as this section documents. Missing the very small non-state firms likely results in an under-estimation of the coefficients on market access measures, since firm selection due to import competition and export access effects happens at the lower end of each location’s productivity distributions. For instance, an increase in CMA will likely make unobserved low-productivity firms exit.

In summary, the reduced-form evidence on the relationship between market access and local productivity and production outcomes is consistent with our theoretical framework, reassuring that our simple model provides a good description of the actual trade dynamics and will likely generate meaningful counterfactuals. In comparison with many previous papers investigating the effect of trade cost shocks (see Goldberg & Pavcnik (2016) for a review), we decompose this effect into two, namely import competition and export access, capture them with respective market access measures, and find evidence of their counteracting effects.

7 Counterfactuals: Evolving Highway Networks

7.1 Fixed-Point Iteration

The reduced-form evidence in Sec.6, while informative, is insufficient for estimating the effect of trade cost changes in general equilibrium because of the inter-location spillovers and the inter-dependence between market access and productivity distribution in the network of locations, as
explained at the beginning of Sec.3. The spillovers and inter-dependence also make it challenging to write moments of interest, for example the mean productivity in an industry after some trade cost shocks, as explicit functions of parameters of the model. Therefore, we conduct fixed-point iteration to characterize counterfactual equilibria: given (observed) initial firm-level and trade cost data, what will the new equilibrium look like if one changes trade costs to a different set?  

1. Compute the initial and endpoint iceberg trade cost matrices, $T_I$ and $T_E$.

2. Denote empirical measures based on initial raw data with subscript 0. Assume everything except trade costs stays the same (in particular, hold FMA’s constant), compute $\{CMA\}_1$ using endline trade cost $T_E$ by Eq.(3). $\{CMA\}_1$ then gives $\{FMA\}_1$ by Eq.(4).

3. By Eq.(6), we find a new set of local productivity cutoffs $\{\varphi^*\}_1$, for every industry-location $j - o$,

$$\frac{\varphi^*_{jo,1}}{\varphi^*_{jo,0}} = \left(\frac{\text{FMA}_{jo,1}}{\text{FMA}_{jo,0}}\right)^{\frac{1}{\sigma_j}}$$

and hence the mass of producing firms

$$\frac{h_{jo,1}S_{jo}}{h_{jo,0}S_{jo}} = \frac{\int_{\varphi^*_{jo,1}}^{\infty} dG_{jo}}{\int_{\varphi^*_{jo,0}}^{\infty} dG_{jo}} = \left(\frac{\varphi^*_{jo,1}}{\varphi^*_{jo,0}}\right)^{-\theta_{jo}}$$

4. By Eq.(8), total firm revenue

$$\frac{R_{jo,1}}{\sigma_j} - c_jE_{jo} = \frac{h_{jo,1}S_{jo}f_{jo}}{h_{jo,0}S_{jo}f_{jo}} \Rightarrow R_{jo,1} = \left(\frac{\text{FMA}_{jo,1}}{\text{FMA}_{jo,0}}\right)^{\frac{\theta_{jo}}{\sigma_j}} R_{jo,0} + \left[1 - \left(\frac{\text{FMA}_{jo,1}}{\text{FMA}_{jo,0}}\right)^{\frac{\theta_{jo}}{\sigma_j}}\right] \sigma_j c_j E_{jo}$$

5. Given trade balance at location level, $\{R\}_1$ gives total expenditure: $X_{jo,1} = \sum_j R_{jo,1}$. $\{R\}_1$ and $\{X\}_1$, together with $\{CMA\}_1$ and $\{FMA\}_1$ computed in Step 2, give $\{CMA\}_2$ and $\{FMA\}_2$ by Eq.(3).

6. Iterate Steps 2 – 5 until both $\{CMA\}$ and $\{FMA\}$ converge.  

Denote empirical measures at fixed point with subscript $F$. Given $\{\varphi^*\}_F$ and $\{\theta\}$, we draw a number of firms from every $j - o$ in proportion to $S_{jo,F}$ and obtain the national distribution of firm productivity and production.  

A similar approach has been formalized by Allen & Arkolakis (2014), and applied in Donaldson & Hornbeck (2016) (see Sec.III.B “Procedure for Counterfactual Simulations” in their online appendix).  

Lacking firm-level data from RoW, we assume that $X_{\text{CMA}}$ and $R_{\text{CMA}}$ stay constant for RoW during the iteration.  

One may also derive explicitly empirical moments to match with raw data, yet it easily becomes messy to aggregate local productivity distributions to the national level.
Note that this method rules out the extensive margin at industry-location level. Baseline “zeros”, i.e. industry-location’s without a single firm at baseline, may see entrants as highway networks expand. Yet we do not observe the mass of firms or total revenue of these baseline zeros, so the above method is inapplicable. Still, baseline zeros do not seem to matter much for our counterfactual characterization. At baseline in 1998, there were 6,672 non-zero’s and 1,561 zeros, 273 of which became non-zero’s but only accounted for 0.82% of the total output in 2007. In other words, the sizable growth in firm production between 1998 and 2007 comes largely from industry-location’s that already had producing firms in 1998, validating the fixed-point iteration approach above.

7.2 Counterfactual: 1998 Firms, 2007 Highways

A key question of policy significance is: how much did the large-scale highway expansion contribute to the observed dramatic productivity and output growth observed between 1998 and 2007 (recall Table 1(A))? In addition to aggregate growth, what about inclusive growth across regions, given that the highways connected relatively developed and underdeveloped prefectures? To answer these questions, we apply 2007 travel time to 1998 firm data, and examine the resulting equilibrium now that only the market access forces associated with highway expansion are at work. Panel A of Table 9 compares this counterfactual equilibrium to the actual 1998 data. Overall, the highway construction between 1998 and 2007 raised aggregate productivity and, less powerfully, reduced productivity dispersion. Production became slightly less concentrated in the largest prefectures, and aggregate firm mass and revenue both increased substantially. This suggests the importance of both the import competition and export access effects of highway connection. On the one hand, unproductive firms in the least productive prefectures (where average firm productivity was very low to begin with) were forced to exit under intense import competition, resulting in higher aggregate productivity and smaller productivity dispersion. On the other hand, more productive prefectures saw a large number of entrants due to market expansion. While the entrants were less productive than their local incumbents, they were still more productive than the exiting firms in very unproductive prefectures. This massive entry then had a relatively small effect on the aggregate productivity level, but a much larger effect on the aggregate number of firms and revenue. The growth of the most productive incumbents also contributed considerably to aggregate revenue growth.

We then compare this counterfactual equilibrium to the actual 2007 data, presenting the results
in Panel B of Table 9. Comparison between the counterfactual and the actual changes shows that
the firm selection mechanism fueled by highway construction alone accounts for about 24% of the
observed productivity growth, and almost 40% of the reduction in productivity dispersion. Highway-
induced changes in market access are less powerful in explaining the observed more-than-doubled
sum of firms and 4-fold increase in aggregate output, accounting for around 16% of the actual
changes.

The aggregate patterns mask enormous heterogeneity across industries and locations. In Table ??, we examine how the counterfactual changes vary by industry and location characteristics at
baseline (in this case, 1998 data). Productivity dispersion decreases more for industries with a
higher share of output in (often inefficient) state-owned enterprises, suggesting that the import
competition effect is stronger where there are initially many inefficient, close-to-exit firms. Highly
productive prefectures tend to see a large number of entrants and a sizable increase in total revenue,
suggesting that the export access effect dominates at the higher end of the productivity distribution.
In contrast, unproductive prefectures tend to see more of their firms exit, and experience a decrease
in total revenue.

We keep in mind that highway expansion was among a myriad of factors that contributed to
the observed evolution of productivity and production distributions. During the 1998-2007 decade,
surviving individual firms experienced substantial productivity growth (Brandt et al., 2012) by
learning from the best performers, both domestic and abroad, and investing in R&D by themselves.
The Chinese economy became increasingly market-oriented as the government reformed SOEs and
pushed for privatization (Chen et al., 2016). China’s admission to the WTO also allowed domestic
firms to interact with global markets in more complex ways than our model assumes. Given more
relevant forces than enumerated here, it is encouraging that our simple model explains a significant
part of the actual evolution of the Chinese manufacturing sector.

8 Conclusion

This paper develops a “market access” approach to studying the geographic distribution of firm
productivity and production in an economy. In the Melitz framework, we distinguish between two
distinct effects, import competition and export access, of trade cost changes, and derive CMA and
FMA measures respectively to capture each effect. We empirically examine how market access forces
shape the distribution of firm productivity and production across locations in China’s manufacturing
sector, taking advantage of the dramatic expansion of highway networks from 1998 to 2007 that brought about substantial reduction in inter-regional trade costs. Consistent with the theoretical framework, we find strong reduced-form evidence that, conditional on FMA, CMA raises local average productivity, shrinks local firms’ output, and make unproductive firms more likely to exit, while FMA works in the opposite direction. We use our model to recover counterfactuals, and find that a significant proportion of the observed productivity growth and reduction in productivity dispersion is attributable to the massive highway construction.

This paper sheds lights on an under-researched role of transportation infrastructure in the course of economic development: lifting inter-regional trade barriers and fostering economic integration in a national market. Our results suggest that a low level of integration may explain the greater productivity dispersion in developing countries than in developed countries, as documented in Hsieh & Klenow (2009), and point to higher marginal returns to transportation infrastructure investments in less economically integrated countries or regions. We emphasize that economic integration generates competing effects on local firms, and firm heterogeneity is essential to evaluating the net benefit. Our “market access” approach highlights the importance of examining economic integration in general equilibrium, taking into account how local economic mass can endogenously respond to lower trade costs, and how such responses propagate through the network of geographic locations in an economy.

Table 4. Industry-Prefecture Total Revenue, Data vs. Model

This set of tables compare the industry-prefecture total revenue between actual data and model-simulated data, for the year 1998.

Table 4(A): Size Groups

Within each of the 29 2-digit industries, we rank prefectures by total revenue, and record the set of prefectures in a certain size group (Top 10, Bottom 40) in simulated data. We then compute the share of these prefectures that fall in the same size group in actual data, and show summary statistics of this share across industries.

<table>
<thead>

<td>13.5</td>
</tr>
</tbody>
</table>

Table 4(B): Geographic Concentration of Production

Within each of the 29 2-digit industries, we rank prefectures by total revenue, and record how much prefectures in a certain size group (largest 5, smallest 20, etc.) account for the industry's aggregate revenue. We show summary statistics of this revenue share across industries.

Notes: (1) Mean productivity is the mean Levinsohn-Petrin output productivity across firms in an industry-prefecture-year.
(2) Total revenue is in billion CNY.
Table 6(A). Market Access and Industry-Prefecture Average Productivity

This table presents panel regressions of industry-prefecture mean productivity on market access measures. "Weighted" refers to mean productivity weighted by firm output, across all firms in an industry-prefecture-year. Market access measures are computed in 3 different ways: (1) "basic" follows the basic definitions in the theoretical framework, using all locations in the economy and contemporary economic mass (firm productivity, revenue, etc.); (2) "distant neighbors" excludes prefectures within 300km of travel distance from the prefecture in question; (3) "baseline mass" restricts the economic mass to baseline (Year 1998).

Table 8. Market Access, Firm Productivity, and Entry & Exit

This table shows how market access affects firm entry and exit. In Columns (1)-(3), we define "firm exit" as an indicator of an individual firm being present at baseline year (2004 here) but not at endline (2007 here), and take the long difference between baseline and endline for market access measures. We categorize firms at baseline into tertiles based on a firm's productivity ranking within its industry. In Column (4), we tag a firm as "entrant" if it is present at endline but not at baseline, and count the number of entrants at industry-prefecture level.

Table 9. Highway Network Expansion: Counterfactual

This table presents results from the counterfactual equilibrium that we arrive at by applying 2007 trade cost to 1998 firm data. This counterfactual describes what would happen had if only the highway-induced market access forces were at work between 1998 and 2007. Panel A compares this counterfactual to 1998 data. Panel B compares this counterfactual to 2007 data, showing how much of the observed evolution of firm productivity and production the highway-induced market access forces can account for.

Maps of highway networks in China, based on ACASIAN GIS data.

Figure 2(A): Highway Networks in 1998

Figure 2(B): Highway Networks in 2007
Figure 3. Rho Estimates and Industry Characteristics

This set of figures show the correlation between estimates of rho, which shows how fast trade cost increases in travel time for an industry, correlates with the industry's characteristics.

Figure 3(A): Rho and Weight-to-value Ratio

Industry-level weight-to-value ratios, in 1k U.S. dollars per metric ton, come from 2007 U.S. Commodity Flow Surveys. We are able to match 21 2-digit industries in CIFD data to CFS industries.
Figure 4: Industry-Prefecture Total Revenue, 1998 Data vs. Model

This bin-scatter plot shows the industry-prefecture total revenue (billion CNY, in natural logs) between actual data and model-simulated data, for the year 1998.

**Notes:** (1) OLS regression of (ln) simulated revenue on actual revenue, standard errors clustered at industry level.
A Appendices

1.1 Data Sources

1.1.1 CIFD

A substantial amount of data work is necessary before empirical analysis. Key issues include standardizing industry codes and address IDs, constructing an unbalanced firm-year panel, deflating nominal variables, etc. (Brandt et al., 2012) provides a comprehensive description of such data work in their online appendix. This paper follows their steps and has largely replicated their results.

We take additional steps to further clean the data. First, we adjust prefecture IDs to the 2004 standard, \(^{32}\) as a large number of prefectures experienced ID changes around 2000. Second, we clean and reformat a series of string variables, including firm name, corporate representative, zip code, telephone number, etc. to identify individual firms. Third, when matching firms over time, at each step, we match firms based on a primary identifier such as firm name or corporate representative, together with a secondary identifier such as starting year or zip code, in order to improve the accuracy of matching.

1.1.2 ACASIAN Data

We obtain highway GIS data from the Chinese Spatio-Temporal Expressway Database maintained by the ACASIAN Data Center at Griffith University in Brisbane, Australia. To construct this database, ACASIAN staff digitized dozens of high-resolution road atlases published by Chinese national and regional authorities of road transportation. The entire database records the evolution of China’s highway networks from 1992 to 2011. For the decade 1998-2007 (due to CIFD availability, as described above), we have nationwide highway maps for 1998, 2000, 2002, 2003, 2005, and 2007.

1.2 Input Market Access (IMA)

This appendix supplements the theoretical framework in Sec.3 with an input channel: as trade costs decline, so will the prices that local firms pay for intermediate inputs from elsewhere. This formalizes the input-output linkages between industries, as firms in industry-location \(j-o\) source

\(^{32}\) Administrative division code, as of Sep. 30 2004, available on NBS website.
inputs from all other industries $k$ to obtain composite intermediate input (similar to Caliendo & Parro (2015)). To highlight the link between input price and transportation cost, we add to the original Melitz set-up how firms source intermediate inputs from other locations. Assume a Cobb-Douglas production function at industry level, for a firm,

$$Y = AK^{\beta_K}L^{\beta_L}M^{\beta_M}$$  \hspace{1cm} (13)

where $Y, K, L, M$ denote output, capital, labor, and materials (intermediate input). Denote the price of capital, labor, materials by $P_K, P_L, P_M$, respectively. To produce $Y$ unit of output, a firm’s cost minimization problem is

$$\min_{K, L, M} P_K \cdot K + P_L \cdot L + P_M \cdot M \text{ s.t. } AK^{\beta_K}L^{\beta_L}M^{\beta_M} \geq Y$$

which implies that, under constant returns to scale ($\beta_K + \beta_L + \beta_M = 1$), the marginal cost of production

$$MC = \frac{Z_Y}{A} P_K^{\beta_K} P_L^{\beta_L} P_M^{\beta_M}$$  \hspace{1cm} (14)

where $Z_Y$ is a constant with only $\beta$’s, not factor prices.

Further assume the composite intermediate input $M_j$ as a Cobb-Douglas aggregate of output from all industries $M_k^j$, again under constant returns to scale,

$$M_j = \prod_k (M_k^j)^{\alpha_k^j} \text{ with } \sum_k \alpha_k^j = 1$$

where $\alpha_k^j$ is the share of industry $k$’s output as industry $j$’s input in the total intermediate input of industry $j$, and empirically comes from the national input-output table. Similarly, cost minimization implies that, for firms in location $o$, the price of this composite intermediate input as a C-D aggregate of $P_{o,M_k^j}$, the prices of output from all industries,

$$P_{M_j,o} = Z_{M_j} \prod_k (P_{o,M_k^j})^{\alpha_k^j}$$

where $Z_{M_j}$ is again a constant (with only $\alpha_k^j$’s, not $P_{o,M_k^j}$’s). Recall that $CMA_{ko}$ is the price index.
of industry $k$’s output at location $o$, $CMA_{ko} = (P_{ko})^{1-\sigma_k}$, we thus define input market access,

$$IMA_{jo} = \prod_k (CMA_{ko})^{\sigma_k/(\sigma_k-1)}$$

(15)

and write the unit/marginal cost of production,

$$\frac{c_{jo}}{\phi_{j,o}} = \frac{Z_{Y_{jo}}(Z_{M_{jo}})^{\beta_{j,M}}}{A_{j,o}}P_{j,o,K}^{\beta_{j,K}}P_{j,o,L}^{\beta_{j,L}}(IMA_{jo})^{-\beta_{j,M}} \propto (IMA_{jo})^{-\beta_{j,M}}$$

(16)

Write this into Eq.(1), and take logs on both sides,

$$\ln r_{j,o} = (\sigma_j - 1) \ln A_{j,o} + \ln FMA_{jo}$$

$$+ (1 - \sigma_j) \left( \ln Z_{C_{jo}} + \beta_{j,K} \ln P_{j,o,K} + \beta_{j,L} \ln P_{j,o,L} - \beta_{j,M} \ln IMA_{jo} \right)$$

(17)

Under the standard assumption in Melitz framework that factor prices are uniform across firms in an industry-location, we simplify the above equation to

$$\ln r_{j,o} = (\sigma_j - 1) \ln A_{j,o} + \delta_{j,o}$$

where $\delta_{j,o}$ is an industry-location specific constant. In our unbalanced firm-year panel data, we observe firm-level revenue $r_{j,o}$, and estimate firm productivity $A_{j,o}$ (say, Levinsohn-Petrin TFPR) based on firm production function Eq.(13). We then run this regression for each industry $j$, with location*year fixed effects, to recover $\sigma_j$. Note that we should use TFPQ rather than TFPR here.

### 1.3 Discussion: Different Transport Modes

One may question how good road travel time is a proxy of trade cost. Cutting road travel time by building highways is one of many approaches to lower trade cost between prefectures: speeding up railway transportation, building more airports . . . , improving port facilities for navigable waters, can perhaps serve the same purpose. In fact, from 1997 to 2007, the Chinese Ministry of Railways implemented 6 speed-up campaigns that raised the average speed of trains from about 50km/h to 120km/h, together with a sizable increase in train capacity (Fang, 2013). Unlike highways, however, railways do not directly connect most prefectures in China, at least by the end of 2007 before the start of the historic high-speed railway boom (and high-speed railways are passenger-dedicated
lines). For robustness, we also confirm that our reduced-form results hold across subsamples of industries with varying proportions of total expenses spent on road transport. Air traffic, by the number of passengers, also increased by around 400% from 2003 to 2010, although the total number of passengers remained minimal in comparison with road traffic. More importantly, air traffic is predominantly about passenger traffic and unlikely very relevant for large volumes of manufactured goods. Waterways connect a fairly small set of prefectures in China, and was generally considered under-utilized in our sample period, in which waterway-associated infrastructure remained quite poor and experienced little upgrading.
